Neisseria meningitidis Has Two Independent Modes of Recognizing Its Human Receptor CEACAM1

Katharina Kuespert*, Alexandra Roth, Christof R. Hauck*

Abstract

Background: Several human-restricted Gram-negative bacteria exploit carcinoembryonic antigen-related cell adhesion molecules (CEACAMs) for host colonization. For example, Neisseria meningitidis engages these human receptors via outer membrane proteins of the colony opacity-associated (Opa) protein family triggering internalization into non-phagocytic cells.

Principal Findings: We report that a non-opaque strain of N. meningitidis selectively interacts with CEACAM1, but not other CEACAM family members. Using functional assays of bacterial adhesion and internalisation, microscopic analysis, and a panel of CEACAM1 deletion mutants we demonstrate that the engagement of CEACAM1 by non-opaque meningococci occurs in a manner distinct from Opa protein-mediated association. In particular, the amino-terminal domain of CEACAM1 is necessary, but not sufficient for Opa protein-independent binding, which requires multiple extracellular domains of the human receptor in a cellular context. Knock-down of CEACAM1 interferes with binding to lung epithelial cells, whereas chemical or pharmacological disruption of host protein glycosylation does not abrogate CEACAM1 recognition by non-opaque meningococci. The previously characterized meningococcal invasins NadA or Opc do not operate in a CEACAM1-independent manner.

Conclusions: The results demonstrate a mechanistically distinct, Opa protein-independent interaction between N. meningitidis and human CEACAM1. Our functional investigations suggest the presence of a second CEACAM1-binding invasin on the meningococcal surface that associates with the protein backbone and not the carbohydrate structures of CEACAM1. The redundancy in meningococcal CEACAM1-binding factors further highlights the important role of CEACAM recognition in the biology of this human-adapted pathogen.

Introduction

The genus Neisseria contains two human-specific pathogens, Neisseria gonorrhoeae and Neisseria meningitidis, which occupy different host niches and cause two distinct diseases. Whereas Neisseria gonorrhoeae is the causative agent of gonorrhea and primarily infects the urogenital tract causing localized inflammation, Neisseria meningitidis is a frequent commensal of the upper respiratory tract, which can cause life-threatening invasive infections, such as septicemia and meningitis [1,2]. To cause disease, meningococci need to traverse the mucosal barrier and enter into the bloodstream. There, the bacteria can multiply rapidly, as a polysaccharide capsule and sialylation of lipooligosaccharide molecules (CEACAMs) for host colonization. For example, Neisseria meningitidis engages these human receptors via outer membrane proteins of the colony opacity-associated (Opa) protein family triggering internalization into non-phagocytic cells.

Principal Findings: We report that a non-opaque strain of N. meningitidis selectively interacts with CEACAM1, but not other CEACAM family members. Using functional assays of bacterial adhesion and internalisation, microscopic analysis, and a panel of CEACAM1 deletion mutants we demonstrate that the engagement of CEACAM1 by non-opaque meningococci occurs in a manner distinct from Opa protein-mediated association. In particular, the amino-terminal domain of CEACAM1 is necessary, but not sufficient for Opa protein-independent binding, which requires multiple extracellular domains of the human receptor in a cellular context. Knock-down of CEACAM1 interferes with binding to lung epithelial cells, whereas chemical or pharmacological disruption of host protein glycosylation does not abrogate CEACAM1 recognition by non-opaque meningococci. The previously characterized meningococcal invasins NadA or Opc do not operate in a CEACAM1-independent manner.

Conclusions: The results demonstrate a mechanistically distinct, Opa protein-independent interaction between N. meningitidis and human CEACAM1. Our functional investigations suggest the presence of a second CEACAM1-binding invasin on the meningococcal surface that associates with the protein backbone and not the carbohydrate structures of CEACAM1. The redundancy in meningococcal CEACAM1-binding factors further highlights the important role of CEACAM recognition in the biology of this human-adapted pathogen.

Introduction

The genus Neisseria contains two human-specific pathogens, Neisseria gonorrhoeae and Neisseria meningitidis, which occupy different host niches and cause two distinct diseases. Whereas Neisseria gonorrhoeae is the causative agent of gonorrhea and primarily infects the urogenital tract causing localized inflammation, Neisseria meningitidis is a frequent commensal of the upper respiratory tract, which can cause life-threatening invasive infections, such as septicemia and meningitis [1,2]. To cause disease, meningococci need to traverse the mucosal barrier and enter into the bloodstream. There, the bacteria can multiply rapidly, as a polysaccharide capsule and sialylation of lipooligosaccharide renders them resistant against complement-mediated killing [3]. Furthermore, N. meningitidis has a propensity to tightly interact with endothelial cells and to cross the blood-brain barrier, resulting in fulminant meningococcal meningitis [4]. Clearly, colonization of the mucosal epithelium is the first step for causing disease, followed by invasion, intracellular persistence and transcytosis [5]. Known meningococcal factors, which promote adhesion to epithelial cells and presumably play a role in colonization are type IV pili, App (adhesion and penetration protein) [6,7], MspA (meningococcal serin protease A) [8], NhhA (Neissierial hia/hsf homologue) [9] and HrpA [10]. Additionally, meningococci express a panel of proteins that not only mediate adhesion, but also promote invasion into host cells, such as colony opacity associated (Opa) proteins, Opc and NadA [11]. NadA belongs to the oligomerically coiled-coil (Oca) family of adhesins and seems to be expressed primarily in hyper-virulent Neisseria meningitidis lineages, but not in Neisseria gonorrhoeae [12]. The cellular receptor for NadA is still unknown – however, there is evidence that the receptor is of protein nature [13]. In contrast to NadA, Opc and Opa proteins belong to class 5 outer membrane proteins. Opc is a phase variable protein, and, though the ope gene is found also in gonococci, the protein is only expressed by meningococci [14]. Opc associates with several host molecules including extracellular matrix proteins, integrins and heparansulfate proteoglycans [15,16,17]. Unlike Opc, Opa proteins are expressed in most meningococcal and gonococcal isolates. Whereas the meningococcal genome encodes up to 4 distinct Opa proteins, gonococci harbour up to 11 copies of ope
Expression of Opa proteins is subject to phase variation due to a RecA-independent insertion or deletion of pentanucleotide repeats within the leader peptide coding sequence, which leads to translational reading frame shifts in the constitutively transcribed ofa genes [19]. In natural settings, phase variation of individual Opa proteins results in a heterogeneous population of bacteria expressing none, one or multiple Opa proteins. Upon culture on agar plates, colonies expressing distinct Opa proteins can be differentiated by their phenotype. Besides a few Opa protein variants that recognize cell surface expressed heparansulphate proteoglycans (Opa HSPG) [20,21], most Opa proteins of diverse strains of Neisseria meningitidis and Neisseria gonorrhoeae recognize one or more members of the carcinoembryonic antigen-related cell adhesion molecule (CEACAM) family (OpaCEA) [22,23,24]. In particular, CEACAM1, CEACAM3, CEA (the product of the CEACAM5 gene) as well as CEACAM6 have been reported to bind to neisserial OpaCEA proteins, and to mediate internalization of the pathogens [25,26]. In this regard, the molecular mechanism of CEACAM3-mediated uptake has been studied in great detail and relies on tyrosine based sequence motifs in the cytoplasmic domain of CEACAM3 [27,28]. Expression of CEACAM3 is restricted to human granulocytes and enables these immune effector cells to phagocytose and eliminate CEACAM-binding microbes [28,29,30]. In contrast to the granulocyte-restricted CEACAM3, CEACAM1 has a broad tissue distribution and is expressed on hematopoetic cells, endothelial cells and epithelial cells [31,32]. CEACAM1 has attracted particular interest as a homophilic and heterophilic cell-cell adhesion molecule, that is involved in several important cellular activities, such as immune modulation, insulin homeostasis, neangiogenesis, tissue homeostasis, and tumor progression [33]. This receptor is expressed in several isoforms due to alternative splicing of the CEACAM1 transcript. The major isoforms are CEACAM1-4L and CEACAM1-4S that possess an extracellular aminoterminal IgV-like domain (N), followed by three IgC2-like domains (A1, B, A2) and a transmembrane domain. CEACAM1-4L and CEACAM1-4S differ in their cytoplasmic domain with CEACAM1-4S having only about ten amino acid residues in the cytoplasm, whereas the long isoform (CEACAM1-4L) has a 71 – 74 residue long cytoplasmic tail. Interestingly, both the long and the short isoform of CEACAM1 internalize bacteria with similar efficiency via a membrane microdomain-dependent uptake mechanism [34]. Though CEACAM1 is a highly glycosylated protein, CEACAM1 binding by neisserial OpaCEA proteins is a direct protein-protein interaction that occurs at the non-glycosylated CCTG-face of the aminoterminal, IgV-like domain. Therefore, the CEACAM1 aminoterminal, IgV-like domain is necessary and sufficient for binding of OpaCEA protein-expressing gonococci and meningococci [35]. On the bacterial side it has been shown, that the two hypervariable extracellular regions of OpaCEA proteins are responsible for CEACAM recognition [36]. However, no clear consensus has emerged, which amino acid sequence determines the adhesive properties of neisserial OpaCEA proteins. Nevertheless, OpaCEA proteins appear as the only neisserial invasins described so far, which bind to CEACAM1.

In the present study we investigated the interaction of Neisseria meningitidis strain MC58 with CEACAMs. Surprisingly, we selected for the absence of Opa protein expression, was still able to specifically interact with CEACAM1. Similar to the binding of OpaCEA protein-expressing meningococci, the interaction with non-opaque N. meningitidis was independent of post-translational carbohydrate modification of the receptor. However, the amino-terminal domain of CEACAM1 was necessary, but not sufficient for this association. Heterologous expression of several known meningococcal invasins did not result in CEACAM1-mediated uptake. Therefore, our data suggest that Neisseria meningitidis MC58 possesses a novel, uncharacterized invasin, which mediates CEACAM1-interaction.

Materials and Methods

Neisserial strains and growth conditions

OpaCEA protein-expressing, non-encapsulated Neisseria meningitidis strain MC58 (AisAΔ, AlgAΔ) (Nm OpaCEA) was obtained from Matthias Frosch (Institut für Hygiene und Mikrobiologie, Universität Würzburg, Germany). The Opa protein-negative derivative of Neisseria meningitidis MC58 (Nm Opa-) was isolated from Nm OpaCEA by visual screening for a non-opaque phenotype using a binocular microscope. OpaΔ2 protein-expressing, non-piliated Neisseria gonorrhoeae strain MS11 (Ngo OpaCEA) and non-opaque, non-piliated N. gonorrhoeae MS11 (Ngo Opa-) were kindly provided by Thomas F. Meyer (Max-Planck-Institut für Infektionsbiologie, Berlin, Germany). Both, Neisseria meningitidis and N. gonorrhoeae were grown as described before [35] on GC agar plates (Difco BRL, Paisley, UK) supplemented with vitamins at 37°C, 5% CO₂. For infection, over-night grown bacteria were taken from GC agar plates, suspended in PBS, and colony forming units (cfu) were estimated by OD₅₅₀ readings according to a standard curve.

Epithelial and endothelial cell lines

Human embryonic kidney epithelial 293T cells (293 cells; ACC-655, German collection of microorganisms and cell cultures, DSMZ, Braunschweig, Germany) were cultured in Dulbecco’s modified Eagle’s medium (DMEM) containing 10% calf serum. African green monkey kidney cells (COS cells) and human hamster ovary cells (CHO K1 cells), as well as stably transfected COS-CEACAM1 and CHO K1-CEACAM1 cells, were obtained from T.F. Meyer (MPI für Infektionsbiologie, Berlin, Germany) and cultured in RPMI containing 10% fetal calf serum. A549 epithelial cells (human alveolar lung adenocarcinoma cells; ATCC CCL87) were cultured in DMEM containing 10% fetal calf serum. Human brain microvascular endothelial cells (HBMEC) [37] were grown in endothelial cell medium (PAA, Pasching, Austria) supplemented with L-glutamine. Cells were grown at 37°C in 5% CO₂ and subcultured every 2-3 days.

Recombinant DNA constructs

Mammalian expression plasmids encoding cDNA of human CEACAM3, CEA, CEACAM6, CEACAM7 or CEACAM8 have been described previously [30]. HA-tagged versions of CEACAM1, CEACAM1 lacking the IgC2-like domains A1, B, A2 (CEACAM1-N) and CEACAM1 lacking the complete cytoplasmic domain (CEACAM1-ΔCT) were described previously [34,38]. CEACAM1-NA1B-variant and CEACAM1-NA1-variant were generated from the HA-tagged version of CEACAM1 by SOEing PCR [39]. For CEACAM1-NA1B-variant, cDNA for NA1B domains was amplified by PCR with the primers CEACAM1-IF-sense (5’-GAAGTTATCAGTCGACACCATGGGGCACCTC-TCAGCCGCC-3’) and C1-Chim-NA1B TM-anti (5’-TAGCTTGCAAGCATGTGGGACCTC-3’). The transmembrane together with the cytoplasmic domain of CEACAM1 was amplified with primers C1-Chim-NA1B-ΔC-sense (5’-GCTGGAACAGGACACACCACCATCATGCTGAAGTA-3’) and HA-stop-CEACAM1-IF-anti (5’-ATGGGTCTAGAAGCTTATTGCACCGTATCTGGAAACGCATGTC-3’). For CEAC-
CAM1-NA1-variant, cDNA for NA1 domains was amplified using primers CEACAM-IF-sense and C1-Chim-NA1-TM-anti (5'-TAGTGTCAGCATGATGCCGTCGCTGCGTTGACAC-3'). The transmembrane and the cytoplasmic domain of CEACAM1 was amplified with the primers C1-Chim-NA1-TM-sense (5'-GGTGCAACCGCGTCATGGCTGCTGCGTTGACAC-3') and HA-stop-CEACAM1-IF-anti. The two resulting fragments from each construct were combined and served as templates for SOEing PCR with primers CEACAM1-IF-sense and HA-stop-CEACAM1-IF-anti. The CEACAM-B/N1-chimera was generated by SOEing PCR using CEACAM1 and CEACAM8 as template, respectively. The aminoterminal domain of CEACAM5 was amplified by PCR with the primers CE8A-IF-sense (5'-GAAGGTTATCATGCTGACCACTGGGGCCCATATCGACCC-3') and CE8A/1-Chimera-anti (5'-GGGGTTGGGGACAGCTGAGTACGCTGAACCTG-3'). The extracellular Igα2, the transmembrane and the cytoplasmic domains of CEACAM1 were amplified by PCR with the primers CE8A/1-Chimera-sense (5'-TTCCAGCTGATCCTGAGC-3') and HA-stop-CEACAM1-IF. The combined fragments served as templates for the SOEing PCR as above. The cDNAs resulting from the SOEing PCRs were cloned into pDNR-CMV using the In-Fusion PCR Cloning Kit (Clontech, Mountain View, CA).

The secreted CEACAM1 construct (sCEACAM1-N encoding the amino-terminal domain of CEACAM1 fused to GFP was described by us [35]. The secreted CEACAM1 construct encoding all extracellular domains of CEACAM1 (sCEACAM1) was generated by PCR with primers CEACAM1-sense and CE1-secret-prot-IF-anti 5'-ATGGTGTCAGCATGATGCCGTCGCTGCGTTGACAC-3' using pcDNA CEACAM1-HA as a template. The same template was used to generate sCEACAM1-NA1B by amplification with primers CEACAM1-IF-sense and CEA1-B-Dom-IF-anti 5'-ATGGTGTCAGCATGATGCCGTCGCTGCGTTGACAC-3'. The amplified cDNAs of sCEACAM1 and sCEACAM1-NA1B were cloned into plDNR-Dual using the In-Fusion PCR Cloning Kit and transferred from pDNR-dual into plPS3'EGFP by Cre-mediated recombination (Creator System, Clontech, Mountain View, CA) allowing eukaryotic expression of secreted, GFP-tagged proteins.

Expression of meningococcal proteins in *E. coli*

The Opa4-CEA- and Opc-expressing *Escherichia coli* strains were described previously [40,41] and kindly provided by T.F. Meyer and Mark Achtman, respectively (Max-Planck Institut für Infektionsbiologie, Berlin, Germany). In order to express NadA, the nadC1 gene was amplified by PCR from chromosomal DNA of *Neisseria meningitidis* MC58 using the primers NadA-MC58-sense (5'-GGGATCCCTATGATGGGGACACCGGACGCTGCGTTGACAC-3') and NadA-MC58-anti (5'-CCGGAATTGTAGGAATGCCCACGATGGCTGCTGCGTTGACAC-3'). Using the primer MC58 and cloned in pET30a (Novagen), NadA was achieved by restriction fragment was cloned into the NheI and AgeI restriction sites of the pET6a (Novagen) and expressed in *E. coli* BL21 (DE3; Novagen), which was induced for protein expression by IPTG. All *E. coli* strains were cultured at 37°C in Luria-Bertani (LB) supplemented with the appropriate antibiotics.

Generation of a lentiviral vector encoding CEACAM1 shRNA

The plasmids pLKO.1 and plasmid pLKO.1 shControl [42] were maintained in *E. coli* STBL4 (Invitrogen, Carlsbad, CA). Using the algorithm Aa(N19) [available online at http://jura.wi.mit.edu/bioc/siRNAext/] we identified sequences that could silence expression of human CEACAM1. According to this prediction, primers shCEACAM1-sense 5'-GGGATCCATTGATTGAGATATGCAATAGGCTCGAGCCTATTGCATATCCTACAATT-3' and shCEACAM1-anti 5'-AATTGTAGAATGATGTCGACTGGGACCGCATATTGCCGATTATGCAATAGGCTCGAGCCTATTGCATATCCTACAATT-3' were synthesized, annealed and cloned into the AgeI and EcoRI site of pLKO.1 generating pLKO.1 shCEACAM1. The correct insertion of the shRNA cassette was verified by sequencing. Production of infectious lentiviral particles and transduction of cells was performed as described previously [43]. Stably transfected cells were selected for 1 week in medium containing 1 μg/ml puromycin.

Generation of CEACAM1-encoding lentiviral particles

To generate a CEACAM1-GFP encoding lentiviral vector, human CEACAM1-4L was amplified from plasmid pcDNA3.1 CEACAM1-4L-HA [38] with the forward primer CEACAM1-AgeI_forward 5'-GAACTGCTAGCACCATGGGGCACCTCTC-3' and reverse primer CEACAM1-AgeI_reverse 5'-GCTAGATGTCATAGGGATACTGC -3' was cloned in the NheI and AgeI restriction sites of the pLL3.7 [44] resulting in an in-frame fusion of CEACAM1 and the GFP coding sequence. Production of infectious lentiviral particles encoding CEACAM1-GFP or GFP and transduction of cells was performed as described previously [45].

Antibodies and reagents

Monoclonal anti-Opa and Opc antibodies (clone 4B12/C11 and clone B306, respectively) were obtained from Mark Achtman (Max-Planck Institut für Infektionsbiologie, Berlin, Germany). Monoclonal antibody against CEACAMs (anti-CEACAM; clone IH1/Fc; recognizing CEACAM1, CEACAM3, CE, and CEACAM6) was purchased from AL-Immunotools (Friesoythe, Germany) and used for immunofluorescence staining and FACS analysis. Monoclonal antibodies against CEACAMs (clone D14/11; recognizing CEACAM1, CEACAM3, CE, and CEACAM6) was purchased from Genovac (Freiburg, Germany) and used for Western Blotting or FACS analysis,
respectively. Monoclonal antibody against the HA-tag (anti-HA; clone 12CA5) or against tubulin (clone E7) were purified from hybridoma cell supernatants. Rabbit antisera against N. gonorrhoeae and N. meningitidis (IG-511) was custom-made by Immunoglobule (Himmeltal, Germany). Rabbit polyclonal anti-GFP antibody was custom generated and purified (Animal Research Facility, Universität Konstanz, Germany). Tunicamycin was obtained from Sigma-Aldrich (Steinheim, Germany), Cy2-labeled concanavalinA (ConA-Cy2) was purchased from Invitrogen (Karlsruhe, Germany).

Transfection of cells, cell lysis, and Western Blot

293 cells were transfected by calcium phosphate precipitation using 4 μg of appropriate cDNA in each case. The transfection efficiency ranged between 30 and 40% as reported [30] and transfected 293 cells were employed in experiments 48 h after transfection. Cell lysis and Western blotting were performed as described [45]. Similar amounts of cell lysate were used for each sample analysed by SDS-PAGE and Western Blotting.

Gentamicin protection assay

Gentamicin protection assays were conducted as described [28]. Cells were seeded at 4×10⁵ cells/well in 24 well plates coated with fibronectin (4 μg/ml). A multiplicity of infection (MOI) of 40 bacteria per cell was routinely used, and after 2 h of infection, extracellular bacteria were killed by 45 min incubation in 50 μg/ml gentamicin in DMEM. Then, cells were lysed with 1% saponin in PBS for 15 min. The samples were diluted with PBS, and the number of viable bacteria was determined by plating suitable dilutions on GC agar. For inhibition studies, cells were treated with appropriate reagents 5 min (NaIO₄), 30 min (ConA-Cy2), or 24 h (tunicamycin) prior to infection. To verify the effect of the treatment, cells were stained with ConA-Cy2 and analysed by flow cytometry using a FACS Calibur (BD Bioscience, Heidelberg, Germany).

Adherence assay

Cells were seeded and infected as described for gentamicin protection assays. After the infection, the cells were gently washed once, before the 293 cells were lysed by addition of 1% saponin in PBS for 15 min. Cell-associated and intracellular bacteria were suspended by vigorous pipetting, and colony forming units were determined by plating of serial dilutions on GC agar. For inhibition studies, cells were treated with appropriate reagents 5 min (NaIO₄), 30 min (ConA-Cy2), or 24 h (tunicamycin) prior to infection. To verify the effect of the treatment, cells were stained with ConA-Cy2 and analysed by flow cytometry using a FACS Calibur (BD Bioscience, Heidelberg, Germany). For the invasion assay, 293 cells were transiently transfected with a CEACAM1-encoding construct or a control vector (pRNA) and CEACAM1 expression was demonstrated by Western blotting (Fig. 1B). Two days after transfection, cells were infected with Opa protein-expressing Neisseria meningitidis MC58 by visual colony screening that should be used as a negative control in our studies. Indeed, the absence of Opa protein expression in this strain could be verified by Western blot using an anti-Opa protein antibody (Fig. 1A). For the invasion assay, 293 cells were transiently transfected with a CEACAM1-encoding construct or a control vector (pDNA) and CEACAM1 expression was demonstrated by Western blotting (Fig. 1B). Two days after transfection, cells were infected with Opa protein-expressing Neisseria meningitidis (Nm OpaCEA) or N. gonorrhoeae (Ngo OpaCEA) as well as with non-opsin strains (Nm Opa-, Ngo Opa-). Following the infection, the amount of viable internalized bacteria was determined by gentamicin protection assays. As expected, OpaCEA protein-expressing gonococci and meningococci were taken up by CEACAM1-expressing cells, whereas there was no invasion of non-opsin gonococci (Fig. 1C). Surprisingly, infection of CEACAM1-transfected cells with Opa protein-negative meningococci resulted in bacterial internalization into the cells. The amount of internalized Opa protein-negative meningococci (2.7×10⁵ cfu/ml) was lower than the amount of internalized OpaCEA-positive meningococci (5×10⁵ cfu/ml), but was comparable to the uptake of OpaCEA-positive gonococci (2.1×10⁵ cfu/ml) by CEACAM1-expressing cells (Fig. 1C). Clearly, control transfected cells, that did not express CEACAM1 on their surface, were incubated in blocking buffer (PBS, 10% fetal calf serum) for 5 min and then stained for extracellular bacteria with a polyclonal anti-Neisseria antibody (diluted 1:100 in blocking buffer). In the case of CEACAM1-transfected 293 cells, CEACAM1 was detected by addition of monoclonal anti-CEACAM antibody (clone IH4Fc diluted 1:100 in blocking buffer). After 1 h, samples were washed twice, treated with blocking buffer (5 min) and incubated for 45 min with Cy3-coupled goat anti rabbit (for bacterial staining) and, if appropriate, with Cy3-coupled goat anti mouse (for CEACAM1 staining) (dilution 1:100). Following two washes samples were incubated for 20 min with 0.1% Triton-X100 to permeabilize cellular membranes. After three washes and 5 min blocking in blocking buffer, samples were incubated with a polyclonal anti-Neisseria antibody (diluted 1:100 in blocking buffer) for 1 h, to detect intracellular and extracellular bacteria. Samples were washed twice, treated with blocking buffer (5 min) and incubated for 45 min with Cy2-coupled (293 cells) or Cy3-coupled (A549, HBMEC) goat anti rabbit antibody. Following three washes, samples were embedded in mounting medium (Dako, Glostrup, Denmark).

All samples were analysed with a Leica TCS SP5 confocal laser scanning microscope (Leica Microsystems, Wetzlar, Germany). Fluorescence signals of triple-labelled specimens were serially recorded with appropriate excitation and emission filters to avoid bleed-through. Images were digitally processed with Photoshop CS (Adobe Systems, Mountain View, CA) and merged to yield pseudo-coloured pictures.

Results

CEACAM1 mediates association and invasion of Opa protein-negative meningococci

Neisseria meningitidis possesses a repertoire of virulence-associated surface structures, which promote bacterial adherence to and invasion into mammalian cells. To date, OpaCEA proteins are the only neisserial proteins known to exploit members of the CEACAM-family to attach to and gain entry into the cell.

The current study was initiated with the aim to compare OpaCEA protein-mediated host cell interaction between gonococci and meningococci. Therefore, we isolated an Opa protein-negative variant of Neisseria meningitidis MC58 by visual colony screening that should be used as a negative control in our studies. Indeed, the absence of Opa protein expression in this strain could be verified by Western blot using an anti-Opa protein antibody (Fig. 1A). For the invasion assay, 293 cells were transiently transfected with a CEACAM1-encoding construct or a control vector (pDNA) and CEACAM1 expression was demonstrated by Western blotting (Fig. 1B). Two days after transfection, cells were infected with Opa protein-expressing Neisseria meningitidis (Nm OpaCEA) or N. gonorrhoeae (Ngo OpaCEA) as well as with non-opsin strains (Nm Opa-, Ngo Opa-). Following the infection, the amount of viable internalized bacteria was determined by gentamicin protection assays. As expected, OpaCEA protein-expressing gonococci and meningococci were taken up by CEACAM1-expressing cells, whereas there was no invasion of non-opsin gonococci (Fig. 1C). Surprisingly, infection of CEACAM1-transfected cells with Opa protein-negative meningococci resulted in bacterial internalization into the cells. The amount of internalized Opa protein-negative meningococci (2.7×10⁵ cfu/ml) was lower than the amount of internalized OpaCEA-positive meningococci (5×10⁵ cfu/ml), but was comparable to the uptake of OpaCEA-positive gonococci (2.1×10⁵ cfu/ml) by CEACAM1-expressing cells (Fig. 1C). Clearly, control transfected cells, that did not express CEACAM1 on their surface,
were not able to internalize any of the bacterial variants under these conditions demonstrating that uptake of Opa protein-negative meningococci occurs only in the presence of CEACAM1.

To further analyse this interesting effect, we performed adhesion assays with Opa-negative meningococci and CEACAM1-transfected cells. In line with their ability to invade in a CEACAM1-dependent manner, the Opa protein-negative meningococci adhered to CEACAM1-expressing cells (Fig. 1D).

These results were unexpected, as Opa proteins are the only known neisserial ligands for CEACAMs. Clearly, the visualized non-opaque strain of N. meningitidis MC58 did not show reactivity in Western Blots with a monoclonal n-Opa protein antibody that detects a conserved epitope in neisserial Opa proteins (Fig. 1A). However, the antigenic properties of Opa protein(s) could have changed in this strain, potentially resulting in expression of Opa proteins not recognized by the anti-Opa-antibody. To investigate, whether this is the case, all ope genes (opa1, opa2, opa3, opa4) encoded in the genome of this MC58-derived strain were cloned under the control of an IPTG inducible prokaryotic expression vector and overexpressed in E. coli. The bacterial lysates were analysed for Opa protein-expression using the same monoclonal anti-Opa-antibody. Importantly, expression of all Opa-proteins derived from N. meningitidis MC58 (Opa1, Opa2, Opa3, or Opa4) could be detected in IPTG-induced E. coli strains (Fig. 1E) suggesting that the used monoclonal anti-Opa-antibody can recognize all Opa-proteins encoded in N. meningitidis MC58. Taken together, even though the isolated meningococcal strain does not express Opa proteins, it exploits CEACAM1 for adhesion to and invasion into the cell. Therefore, Opa-negative meningococci harbour an additional adhesin mediating interaction with CEACAM1.

CEACAM1 – but not other members of the CEACAM family - mediates uptake of Opa protein-negative meningococci

Previous results indicated that Opa proteins of pathogenic Neisseria can recognize several members of the CEACAM family, namely CEACAM1, CEACAM3, CEA and CEACAM6. Therefore we wondered, whether the Opa protein-negative meningococcal strain can also bind to additional members of the CEACAM-family. Accordingly, 293 cells were transfected with plasmids encoding CEACAM1, CEACAM3, CEA, CEACAM6, CEACAM7, CEACAM8 or with the empty control vector (pcDNA) and infected for two hours with either non-opaque (Nm Opa-) or Opa protein-expressing N. meningitidis (Nm OpaCEA), respectively. Gentamicin protection assays showed, that CEACAM1, but not other members of the CEACAM-family, was able to mediate internalization of Opa protein-negative meningococci (Fig. 2A). In contrast, OpaCEA, protein-positive meningococci were internalized by CEACAM1- and CEACAM6-expressing cells (Fig. 2B). Neither Opa-positive, nor Opa-negative meningococci were internalized by 293 cells transfected with an empty control vector (pcDNA) (Fig. 2A and B). These results suggest, that Opa-negative meningococci specifically interact with CEACAM1, but do not recognize other members of the CEACAM family.

Microscopic analysis of CEACAM1-mediated uptake of Opa protein-negative meningococci

To further confirm that CEACAM1 mediates internalization of Opa protein-negative meningococci, we performed confocal laser scanning microscopy to unambiguously detect intracellular bacteria. Accordingly, 293 cells were transfected with CEACAM1 or the empty control vector (pcDNA). Cells were infected for two hours with Opa protein-negative (Nm Opa-) or Opa protein-positive meningococci (Nm OpaCEA) and fixed. Samples were stained to distinguish between intracellular bacteria (stained with Cy3) and extracellular bacteria (stained with Cy2 and Cy5), and to detect CEACAM1. Confocal laser scanning microscopy revealed that both, Opa protein-positive and -negative meningococcal strains. As expected, control transfected cells (pcDNA) did not show association with the bacteria. Taken together, these data corroborate the findings of the adhesion assays and gentamicin protection assays and demonstrate that CEACAM1 can mediate uptake of Opa protein-negative meningococci.

Different epithelial cell lines mediate CEACAM1-dependent internalization of Opa protein-negative meningococci

A CEACAM1-mediated uptake of Opa protein-negative N. meningitidis MC58 has not been observed previously, when CEACAM1-transfected CHO cells were used [46]. To exclude that internalization of non-opaque meningococci via CEACAM1 is an effect specific for transfected 293 cells, additional cell lines, such as CHO K1 cells and COS7 cells were used for CEACAM1-dependent internalization studies. Similar to 293 cells, these cells do not express any CEACAM family members endogenously. To analyze CEACAM1-mediated uptake, COS cells or CHO cells stably expressing human CEACAM1 or transfected with a control vector (Fig. 3B) were infected with Opa protein-negative meningococci at an MOI of 40. After two hours of infection, the amount of intracellular viable bacteria was determined by gentamicin protection assays. Both, CEACAM1-expressing CHO cells and CEACAM1-expressing COS cells displayed internalization of Opa protein-negative meningococci, whereas control-transfected CHO cells, barely any intracellular meningococci were observed (Fig. 3C). Therefore, CEACAM1-mediated uptake of Opa protein-negative meningococci is not restricted to 293 cells and can be mediated by several CEACAM1-expressing cell lines.

Non-opaque meningococci bind in a CEACAM1-dependent manner to cells derived from meningococcal target tissues

Meningococci colonize the mucosal surface of the nasopharynx and can interact with endothelial cells of the blood-brain barrier during meningococcal disease [4]. To test, if Opa protein-negative meningococci are able to interact with CEACAM1 present on target tissues, we employed the adenocarcinoma cell line A549 derived from lung alveolar epithelium. These cells endogenously express CEACAM1, CEA and CEACAM6 [47] (Fig. 4A). To modulate CEACAM1 levels in these cells, we transduced A549 cells with a lentiviral vector encoding short hairpin RNA (shRNA) directed against human CEACAM1 (shCEACAM1). Indeed, CEACAM1 expression was suppressed by more than 50% in the shCEACAM1 cells compared to untransduced cells or compared to A549 cells transduced with a non-targeted, irrelevant shRNA (shControl) (Fig. 4A, left panel). Despite the remaining presence of CEA and large amounts of CEACAM6 (Fig. 4A, right panel), knockdown of CEACAM1 in shCEACAM1-transduced A549 cells led to a significantly reduced cell association by non-opaque meningococci (Fig. 4B and C).

To further analyse the role of CEACAM1 recognition for target cell interaction, we employed human microvascular endothelial cells (HBMECs). Unstimulated primary endothelial cells do not express CEACAMs, but a strong upregulation of CEACAM1 is
observed upon stimulation with pro-inflammatory cytokines such as TNFα, which is induced during meningococcal infection [48]. Accordingly, we transduced HBMECs with a lentiviral vector encoding CEACAM1-GFP or a control virus encoding GFP. Endothelial cells were infected with opaque or non-opaque meningococci and the cell association and internalization was evaluated by immunofluorescence microscopy (Fig. 4D). Both cell-association and internalization of meningococci were strongly increased upon CEACAM1 expression and this was true for OpaCEA protein-expressing and non-opaque bacterial variants (Fig. 4D and E). Internalization of meningococci occurred to a significant degree only in cells expressing CEACAM1, again

CEACAM1-Binding Meningococci

Figure 2. CEACAM1 – but not other members of the CEACAM family - mediates uptake of Opa protein-negative meningococci. 293 cells were transfected with constructs encoding CEACAM1, CEACAM3, CEA, CEACAM6, CEACAM7, CEACAM8 or an empty control plasmid (pcDNA). Two days after transfection cells were infected for 2 h with (A) Opa protein-negative meningococci (Nm Opa-) or (B) Opa protein-positive meningococci (Nm OpaCEA) and the number of internalised bacteria was determined by gentamicin protection assays. Results represent mean ± standard deviation of three independent experiments done in triplicate. Shown is the percentage of recovered bacteria compared to CEACAM1-expressing cells.
doi:10.1371/journal.pone.0014609.g002

CEACAM1-mediated uptake of Opa protein-negative meningococci is independent of carbohydrate moieties

CEACAM1 is a highly glycosylated receptor. Whereas pathogens such as OpaCEA protein-expressing Neisseriae, Moraxella catarrhalis, or Haemophilus influenzae recognize protein determinants of CEACAM1 [49,50,51,52], several enterobacteria associate with carbohydrate moieties of the receptor [33,54]. As Opa protein-negative meningococci must employ a novel adhesin for CEACAM1 binding, we were interested whether glycosylation of CEACAM1 is essential for this interaction. To influence the level of receptor glycosylation, CEACAM1 transfected cells or control transfected cells were pre-treated with tunicamycin, an inhibitor of N-glycosylation, or NaIO4, which mediates oxidation of carbohydrate cis-diol-groups to aldehyds. Untreated cells served as a negative control. The decrease in surface glycosylation after pretreatment was investigated by flow cytometry using the Cy2-labeled plant lectin concanavalin A (ConA-Cy2), which recognizes α-mannopyranosyl- and α-glucopyranosyl-residues. Indeed, pretreatment of cells with tunicamycin (2 μg per 4×10⁶ cells) as well as treatment of cells with the oxidant NaIO₄ (50 mM) strongly reduced the presence of ConA-binding carbohydrate moieties (Fig. 5A and C). Furthermore, NaIO₄ treatment increased the mobility of CEACAM1 upon SDS-gel electrophoresis demonstrating the successful oxidation of terminal carbohydrate residues (Fig. 5C). However, treatment of CEACAM1-expressing cells with tunicamycin or NaIO₄ did not influence binding and internalization of Opa protein-negative meningococci (Fig. 5B and D). As observed before, there was no internalization in control transfected cells (Fig. 5B and D). To further analyse the involvement of carbohydrate moieties in CEACAM1 mediated uptake, we blocked surface-located α-mannopyranosyl- and α-glucopyranosyl-residues by preincubation of CEACAM1-transfected cells with ConA-Cy2 at a concentration of 15 μg/1.5x10⁶ cells. This concentration was sufficient to saturate all ConA-interacting carbohydrate-structures located on the surface of the cells (Fig. 5E). Again, blocking of surface-located α-mannopyranosyl- and α-glucopyranosyl-residues did not influence CEACAM1-mediated uptake of Opa protein-negative meningococci (Fig. 5F).

Together, these data suggest, that CEACAM1-mediated uptake of Opa protein-negative meningococci does not involve carbohydrate structures of the receptor.

CEACAM1-mediated uptake of Opa protein-negative meningococci requires several extracellular domains of the receptor

Human CEACAM1 is a receptor recognized by diverse adhesins of several bacterial pathogens [33]. For Opa protein-mediated interactions, the amino-terminal domain of CEACAM1 is necessary and sufficient for binding. Therefore, we were interested, which of the extracellular domains of the receptor were needed for association with the putative CEACAM1-binding adhesin of Opa-negative meningococci. Accordingly, we generated a panel of CEACAM1-constructs with a varying number of extracellular domains (Fig. 6A). The constructs encompassed the IgV-like amino-terminal domain (N) of CEACAM1, followed by none (CEACAM1-N), one (CEACAM1-NA1), or two (CEACAM1-NA1B) IgG2-like extracellular domains of the receptor, fused to the transmembrane and cytoplasmic domain. In addition, a chimeric protein composed of the amino-terminal domain of CEACAM8 – which does not interact with any CEACAM-binding adhesin or with Opa protein-negative meningococci – followed by the IgG2-like, transmembrane and cytoplasmic domain of CEACAM1 (CEACAM8-N/1). All constructs contained a carboxy-terminal HA-tag for detection. Similar to wildtype CEACAM1 and CEACAM1 lacking the cytoplasmic domain (CEACAM1-ACT) these constructs were expressed in 293 cells with the expected size (Fig. 6B). Gentamicin protection assays revealed that neither Opa protein-positive, nor Opa protein-negative meningococci were internalized by the CEACAM8-N/1-chimeric protein, demonstrating the importance of the amino-terminal domain of CEACAM1 for bacterial internalization in both cases (Fig. 6C and D). However, the CEACAM1 mutants with deletions in the extracellular IgG2 domains showed a distinct pattern of interaction with either Opa protein-positive or Opa protein-negative N. meningitidis. Whereas opaque meningococci were internalized to the same extent by all CEACAM1 constructs demonstrating that similar to OpaCEA protein-expressing pathogens, non-opaque N. meningitidis can interact with target cells in a CEACAM1-dependent manner (Fig. 4D–F).
harbouring the amino-terminal domain of CEACAM1 (CEA-CAM1, CEACAM1-NA1B-variant, CEACAM1-NA1-variant, CEACAM1-N-variant, CEACAM1-D), internalization of Opa protein-negative meningococci was strongly affected by a reduction in the number of IgC2-like extracellular domains of CEACAM1 (Fig. 6C and D). These data demonstrate that optimal CEACAM1-mediated invasion of Opa protein-negative meningococci seems to depend on multiple extracellular domains of this receptor. The amino-terminal domain of CEACAM1 is necessary (no invasion via CEACAM8-N/1-chimera), but not sufficient (no invasion via CEACAM1-N-variant) for efficient uptake of Opa protein-negative meningococci.

Soluble CEACAM1 extracellular domains do not bind to non-opaque meningococci

CEACAM1 forms parallel cis-dimers in the membrane that are supported by the extracellular IgG2-like domains [55]. To test, if such a particular tertiary and quaternary structure of CEACAM1 might be required to allow binding of Opa protein-negative meningococci, soluble forms of CEACAM1 (sCEACAM1) that encompass either one or multiple extracellular domains were generated (Fig. 6E). These proteins were expressed in 293 cells and the cell-free supernatants were used in pull-down analyses with either non-opaque or OpapCEA protein-expressing meningococci or the corresponding gonococcal variants. As expected, both OpapCEA protein expressing neisserial strains associated with all soluble CEACAM1 variants (Fig. 6E). However, neither non-opaque gonococci nor non-opaque meningococci were able to precipitate any of the CEACAM1 proteins in this assay format (Fig. 6E). These results are in agreement with previous analyses using non-opaque meningococci or gonococci together with soluble CEACAM1 receptor domains [35]. Furthermore, these results indicate that the overall tertiary and/or quaternary structure of CEACAM1 on the cell surface is critical to provide a binding interface for non-opaque meningococci.
Figure 4. Non-opaque meningococci bind in a CEACAM1-dependent manner to cells derived from meningococcal target tissues.

A) A549 cells were transduced with the indicated lentiviral vectors encoding an irrelevant shRNA (shControl) or a CEACAM1-targeted shRNA (shCEACAM1) or were left without virus. Transduced cells were analysed by flow cytometry with a CEACAM1/CEA-specific monoclonal antibody (clone 4/3/17). The negative control was stained with the Cy2-coupled secondary antibody only (gray curve). Whole cell lysates (WCL) of the cells were probed by Western blotting with monoclonal CEACAM-antibody (clone D14HD11; upper panel) or with monoclonal anti-tubulin antibody (lower panel). Bands derived from CEA, CEACAM1, or CEACAM6 are indicated on the right side.

B) shControl- or shCEACAM1-transduced A549 cells were infected with non-opaque meningococci at an MOI of 30 for 3 h. Cell-associated bacteria were stained with a polyclonal antiserum (green) and cells were visualized by differential interference contrast (transmission). Bars represent 10 µm.

C) Cell-associated bacteria were detected as in B) and counted. The line represents the median number of cell-associated bacteria and boxes represent the 25%/75% percentile from 30 cells in each sample. Groups were compared by Wilcoxon’s signed rank test, * p < 0.05.

D) Human brain microvascular endothelial cells (HBMECs) were transduced with a GFP- or a CEACAM1-GFP encoding lentivirus. Transduced cell populations were infected with OpaCEA-expressing (Nme OpaCEA) or non-opaque (Nme Opa-) N. meningitidis at an MOI of 30 for 3 h. Samples were differentially stained with polyclonal antiserum against N. meningitidis to differentiate extracellular (arrowhead) and intracellular (small arrow) bacteria. Transduced cells are detected by their GFP signal. Bars represent 10 µm.

E) Samples from D) were enumerated for intracellular meningococci as in C).

F) Whole cell lysates (WCL) of virus transduced cells from D) were probed with an anti-GFP antibody to demonstrate expression of CEACAM1-GFP.

Figure 5. CEACAM1-mediated uptake of non-opaque meningococci is independent of receptor glycosylation. (A–F) 293 cells were transfected with an empty control vector (pcDNA) or HA-tagged CEACAM1. (A, B) Cells were treated with tunicamycin (+Tun; 2 μg/ml) 24 h prior to infection or were left untreated (-Tun). A) Cells were stained with concanavalin-Cy2 (ConA-Cy2) to label surface glycoproteins or were left unstained and then analysed by flow cytometry. B) Cells were infected with Opa-negative meningococci and the number of internalized bacteria was determined by gentamicin protection assays. Results represent mean ± standard deviation of three independent experiments done in triplicate and show the percentage of recovered bacteria in comparison to CEACAM1-expressing cells in the absence of Tunicamycin. (C, D) Transfected 293 cells were fixed and incubated with NaIO₄ (50 mM) for 5 min at 37 °C in the dark or were left untreated. As a further control, unfixed cells, which were not treated with NaIO₄, were used. C) Cells were analysed for surface glycoproteins as in A) and whole cell lysates (WCL) of pcDNA or CEACAM1-HA transfected cells with or without NaIO₄ treatment were probed with anti-HA-tag antibodies. The size change upon NaIO₄ treatment is indicated by arrowheads. D) Cells were infected with Opa protein-negative meningococci and the number of internalized bacteria was determined as in B). (E, F) Transfected 293 cells were incubated with the indicated concentrations of concanavalin-Cy2 (ConA-Cy2) to saturate α-mannopyranosyl- and α-glucopyranosyl residues. E) Cells were analysed by flow cytometry. F) Cells were treated (+ConA) or not (-ConA) with 15 μg ConA-Cy2, infected with Opa protein-negative meningococci and employed in gentamicin protection assays as in B).

Figure 6. CEACAM1-mediated uptake of Opa-negative meningococci requires multiple extracellular immunoglobulin domains. (A) Schematic drawing of CEACAM1, CEACAM1-mutants and the CEACAM8/CEACAM1 chimera. CEACAM1-mutants (CEA1-NA1B, CEA1-NA1, CEA1-N) are composed of an amino-terminal IgV-like domain (N) and a variable number of IgC2-like domains (A1, B, or A2). The CEA1-ΔCT mutant lacks the cytoplasmic domain and in the CEACAM8/CEACAM1 chimera (CEA8N/1) the IgV-like, amino-terminal domain of CEACAM1 is exchanged with the corresponding domain of CEACAM8. All constructs harbour a carboxy-terminal HA-tag. (B) Expression of CEACAM1, CEACAM1-mutants and CEA8N/1 in whole cell lysates (WCLs) of transfected 293 cells is analysed by Western blotting with a monoclonal anti-HA-tag antibody. (C, D) 293 cells transfected with the indicated constructs were infected for 2 h with C) Opa protein-negative meningococci (Nm Opa-) or D) with Opa protein-positive meningococci (Nm OpaCEA). Internalised bacteria were determined by gentamicin protection assays. Results represent mean ± standard deviation of three independent experiments done in triplicate and show the percentage of internalized bacteria compared to CEACAM1. (E) The indicated soluble GFP-tagged CEACAM1 variants were produced in 293 cells and the cell culture supernatants were used in pull-down assays with Opa protein-negative (Opa-) or Opa protein-positive (OpaCEA) meningococci (Nm) or gonococci (Ngo). Precipitates were probed with polyclonal anti-GFP antibody to detect bacteria-associated CEACAM1 (left panel). The presence of equal amounts of the sCEACAM1 variants in the supernatants (Supp) was verified by blotting with GFP-antibodies (middle panel). The Opa phenotype of the used bacteria was analysed by Western blotting with monoclonal anti-Opa protein antibody (right panel).

Known meningococcal invasins do not contribute to CEACAM1-mediated internalization of non-opaque meningococci

Several adhesive proteins of meningococci have been identified [11]. Whereas type IV pili, App, MspA, HrpA and NhaA promote adherence to host cells, Opa proteins, Opc and NadA have been shown to additionally trigger entry into mammalian cells and to function as invasins. In a candidate approach to elucidate the CEACAM1-directed invasin of non-opaque meningococci, we analysed the contribution of NadA and Opc in this internalization process.

Therefore, CEACAM1 transfected cells or control transfected cells were infected for two hours with E. coli expressing either NadA or Opc or the parental E. coli strain at an MOI of 40. Bacterial uptake was then evaluated by gentamicin protection assays (Fig. 7A). Cells infected with OpaCEA protein-expressing gonococci served as a positive control (Fig. 7B). The expression of the invasins in the E. coli strains was confirmed by Western blot (Opc) or by SDS-PAGE (NadA) (Fig. 7C). As expected, infection of CEACAM1-transfected cells with OpaCEA protein-expressing bacteria resulted in efficient internalization (Fig. 7B). Infection of 293 cells with E. coli NadA or the E. coli control strain did not result in bacterial internalization and this was unchanged upon CEACAM1 expression (Fig. 7A), suggesting that the NadA receptor is not present in 293 cells and that CEACAM1 is not recognized by this bacterial invasin. In contrast, Opc-expressing E. coli invaded control cells as well as CEACAM1-expressing cells at similar levels (Fig. 7A). Clearly, the lack of increased invasion of Opc E. coli into CEACAM1-expressing cells indicates that this invasin is not involved in CEACAM1-mediated uptake. Therefore, these data suggest that N. meningitidis MC58 expresses a novel, undescribed invasin, which utilizes CEACAM1 as a cellular receptor to gain entry into mammalian cells.

Discussion

Bacterial adhesion to epithelial cells is of prime importance in mucosal colonization. However, binding of bacterial adhesins to host receptor molecules may also lead to tissue invasion, a likely pre-requisite for dissemination. In the case of N. meningitidis, an array of outer membrane molecules, such as Opc, NadA and Opa proteins can promote bacterial invasion into host cells [11]. Opa proteins bind to members of the CEACAM family and have been the only known Neisserial ligands for these cellular receptors [32]. In the current study we performed invasion studies with an Opa protein-negative derivative of the meningococcal stain N. meningitidis MC58. Surprisingly, we found that this strain was able to bind to and invade human cells in a CEACAM-dependent manner. Opa protein-negative N. meningitidis specifically interacted with CEACAM1, but not with other members of the CEACAM family. Hence, we postulate that this Opa protein-negative meningococcal strain must possess a second, CEACAM1-binding invasin, distinct from Opa proteins.

Previously, we have investigated receptor recognition by Opa protein-expressing and Opa protein-negative N. meningitidis using the soluble amino-terminal Ig-like domains of various human CEACAMs including CEACAM1 [35]. In these former studies, we did not observe an interaction of Opa protein-negative meningococci with CEACAM1. However, the fact that receptor engagement by the second CEACAM1-binding meningococcal adhesin requires multiple extracellular domains of CEACAM1 explains our previous negative results. In addition, other scientists examined the interaction of an Opa protein-negative strain of N. meningitidis MC58 with CEACAM1 by performing receptor overlay assays with a recombi-
receptor. Furthermore, the aminoterminal domain of CEACAM1 is necessary for association with both OpaCEA protein-expressing and Opa protein-negative meningococci. However, in contrast to OpaCEA protein-expressing Neisseriae or UspA1 of Moraxella catarrhalis, the aminoterminal domain alone is not sufficient for internalization of non-opaque meningococci, as efficient uptake requires several extracellular domains of CEACAM1. This is reminiscent of the situation with typeable and non-typeable H. influenzae, where in most cases the aminoterminal IgV-like domain of CEACAM1 is necessary, but not sufficient for binding, which requires additional IgC2-domains [51]. Though the exact CEACAM1-binding determinants of P5 have not been elucidated, the protein-protein interaction between the Haemophilus adhesin and its host receptor is sensitive to mild denaturation [51] suggesting again that a specific tertiary or quaternary structure of the complete extracellular domain of CEACAM1 is critical.

The expression of multiple, independent ligands for CEACAM1 suggests that targeting of this receptor may be a key element in colonization and pathogenesis of N. meningitidis. Interestingly, engagement of CEACAM1 by meningococci can enhance the matrix adhesion of infected host cells, a process that could counteract the exfoliation of superficial cells in a squamous or stratified epithelial tissue [38]. Indeed, it has been shown recently that engagement of CEA on the mucosal surface of the murine urogenital tract interferes with the exfoliation of superficial epithelial cells, thereby promoting bacterial colonization of this tissue [43]. This process depends on the upregulation of an additional host protein, CD105, which promotes integrin activation and increased adhesion of the infected epithelial cells to the extracellular matrix [43]. As CD105 upregulation is also induced in human epithelial cells upon stimulation of CEACAM1 by CEACAM binding Neisseria [38], the presence of several CEACAM1-binding adhesins might be highly advantageous during the initial host colonization. Furthermore, an alternative, Opa protein-independent system for CEACAM1-binding could allow the bacteria to exploit the immunosuppressive functions of

**Figure 7. Known meningococcal invasins do not contribute to CEACAM1-mediated internalization of non-opaque meningococci.**

(A) 293 cells were transfected with pcDNA CEACAM1-4L-HA or with the empty control vector (pcDNA). Two days after transfection, cells were infected for 2 h with E. coli strains recombinantly expressing NadA, Opc, or the parent strain. The number of internalised bacteria was determined by gentamicin protection assays. Results represent mean ± standard deviation of three independent experiments done in triplicate and show the percentage of recovered bacteria compared to CEACAM1. (B) Cells as in (A) were infected with OpaCEA-expressing gonococci (Ngo OpaCEA) and the number of internalised bacteria was determined as in (A). (C) Expression of recombinant NadA and Opc in E. coli. Expression of Opc was analysed in bacterial lysates by Western Blot using monoclonal anti-Opc antibody. Expression of recombinant NadA in E. coli was analysed by SDS-PAGE after induction with IPTG. The multimeric, functional form of NadA is indicated (arrow). As a control, non-induced E. coli or E. coli not transformed with recombinant proteins were used.
