A general strategy for colloidal stable ultrasmall amorphous mineral clusters in organic solvents†

Shengtong Sun,‡ Denis Gebauer and Helmut Cölfen*

While nature exerts precise control over the size and chemical composition of minerals, this is still a challenging task for artificial syntheses. Despite its significance, until now, there are still no reports on colloidal mineral nanoparticles in the subnanometer range. Here we developed a general gas diffusion strategy using 10,12-pentacosadioic acid as a ligand and ethanol as a solvent to fabricate stable amorphous mineral clusters with a core size of less than 2 nm. First discovered for CaCO₃, the method was successfully extended to produce monolayer protected clusters of MgCO₃, SrCO₃, Eu₂(CO₃)₃, Tb₂(CO₃)₃, Ce₂(CO₃)₃, Ca₃(PO₄)₂, Ca₃C₂O₄ and their hybrid minerals, Ca₄Mg₃(CO₃)₂ and Ca₄(CO₃)₂(PO₄)₂. All the mineral clusters can be well dispersed in organic solvents like toluene, and are stable for a long period without further crystallization. Our work paves a way for the artificial synthesis of colloidal mineral clusters, which may have various uses in both fundamental research and industry.

Introduction

Natural minerals, abiotic or biotic, possess a diversity of functions due to their complex morphologies, chemical compositions, crystalline forms as well as hierarchical structures. During formation, all minerals go through a nanophase stage, which, in most cases, is transitional.† Stopping the nanophase evolution of minerals on the nanoscale size range can produce mineral nanoparticles. Owing to the variation of atomic and electronic structures with size, mineral nanoparticles behave distinctly from their macroscopic counterparts, often with superior physical and chemical properties. In the case of biominerals, living organisms exert precise control over the mineral size, shape and structure, and it is still challenging to synthetically gain a similar control.‡ Various methods such as biomimetic synthesis,§ microemulsion,‖ hydrothermal reaction,‖ postsynthesis,‖ and polymer-templating§ have been reported to fabricate colloidal mineral nanoparticles with different shapes and sizes. However, none of the previous efforts have downsized mineral particles to the subnanometer level or even clusters, due to poor control over inherent severe ionic association, although clusters with sizes less than 2 nm, in particular monolayer-protected clusters, have shown more advantages than larger particles.¶ For example, in the case of noble metals like Au or Ag, the alkanethiolate or alkanecarboxylate clusters are stable in air and behave like “molecules”, i.e., they can be repeatedly isolated from, and redissolved in common organic solvents without irreversible aggregation or decomposition.‖

On the other hand, in recent years, arising evidence suggests the wide existence of stable pre-nucleation or primary clusters as dissolved precursors during mineral formation, which are involved in a new concept of “non-classical” nucleation/crystallization.¶,¶,¶,¶ Pre-nucleation clusters have been found either experimentally or by modelling the nucleation of calcium carbonate (CaCO₃),¶,¶,¶,¶ calcium phosphate,¶,¶,¶ magnetite,¶,¶ silica,¶,¶ amino acids,¶,¶ quantum dots,¶,¶,¶ YVO₄,¶ NaClO₃,¶,¶,¶,¶ YVO₄,¶,¶,¶,¶ 1,3,5-tris(4-bromophenyl)benzene,¶,¶ and many more. Analytical ultracentrifugation (AUC) measurements confirmed the presence of pre-nucleation clusters even in salts of simple monovalent ions like NaCl and Li.¶,¶ Although pre-nucleation clusters were found to be highly dynamic for CaCO₃,¶,¶ they provide a direct way to produce colloidal mineral clusters by stopping the nucleation/growth process at the very early stage by stabilization.¶,¶ In our previous papers, we showed that a gas diffusion method using a unique amphiphilic ligand, 10,12-pentacosadienioic acid (PCDA, structure shown in Scheme 1), as a ligand and ethanol as a solvent, can produce well-defined
monolayer protected CaCO3 clusters.\textsuperscript{27,28} The amorphous CaCO3 core with a size of \textasciitilde 1.4 nm contains only 7 CaCO3 units which are as few as that approximately contained in the primitive unit cell of calcite, and in that a proto-calcite short-range order can even be identified but with a relatively high degree of disorder. Herein, we further explored the applicability of this method to other minerals, and we found that this method can be a general strategy to prepare stable mineral (carbonate, phosphate, and oxalate) clusters as well as their hybrid clusters.

**Experimental**

**Synthesis of mineral clusters**

For carbonate-based mineral clusters, the procedure is similar to the method for CaCO3 clusters.\textsuperscript{29} In brief, 10 mM cation salt (MgCl\textsubscript{2}, 12H\textsubscript{2}O, SrBr\textsubscript{2}, 6H\textsubscript{2}O, EuCl\textsubscript{3}, 6H\textsubscript{2}O, TbCl\textsubscript{3}, 6H\textsubscript{2}O, or CeCl\textsubscript{3}) and 4 mM 10,12-pentacosadiynoic acid (PCDA) were dissolved in 40 mL of ethanol in a vial. Note that PCDA dissolved in ethanol must be filtrated with a 0.45 μm PTFE filter to remove oligomeric impurities. The vial was then sealed with parafilm and three pinholes were punctured allowing for gas diffusion. Three glass bottles filled with 10 mL of crushed (NH\textsubscript{4})\textsubscript{2}CO\textsubscript{3} powder and covered with parafilm, punctured with three pinholes, were put together with the reaction vial in a desiccator. After three days of diffusion, the precipitate found at the bottom of the vial was collected by centrifugation (9000 rpm, 5 min) and then dissolved in a small amount of toluene with the assistance of ultrasonication, which resulted in a transparent solution. The product was further precipitated by adding a large volume of ethanol. This process was repeated at least six times to remove all free PCDA and any possible salt impurities. The final solid was dissolved in toluene for storage.

For the Ca\textsubscript{4}x(PO\textsubscript{4})\textsubscript{y} cluster, 10 mM CaCl\textsubscript{2}, 4 mM PCDA and 6 mM polyphosphoric acid (PPA, concentration based on repeat unit) were dissolved in 40 mL of ethanol. The reaction vial was put in a desiccator together with another bottle filled with 2 mL of NH\textsubscript{4}OH aqueous solution (25%). Both the reaction vial and the bottle with NH\textsubscript{4}OH were covered with parafilm with three punctured pinholes followed by gas diffusion in a desiccator. After three days of diffusion, the washing process was the same as described above for the carbonate-based minerals.

For Ca\textsubscript{2}C\textsubscript{2}O\textsubscript{4} clusters, PPA was replaced by 4 mM dimethyl oxalate. The rest of the method is the same as for the Ca\textsubscript{4}x(PO\textsubscript{4})\textsubscript{y} cluster.

For Ca\textsubscript{5}Mg\textsubscript{3}(CO\textsubscript{3})\textsubscript{4} clusters, 5 mM CaCl\textsubscript{2}, 5 mM MgCl\textsubscript{2} and 4 mM PCDA were mixed in ethanol. Gas diffusion occurred from the decomposition of (NH\textsubscript{4})\textsubscript{2}CO\textsubscript{3}.

For Ca\textsubscript{6}(CO\textsubscript{3})\textsubscript{3}(PO\textsubscript{4})\textsubscript{3} clusters, 10 mM CaCl\textsubscript{2}, 4 mM PCDA and 3 mM PPA were dissolved in ethanol. Gas diffusion occurred from the decomposition of (NH\textsubscript{4})\textsubscript{2}CO\textsubscript{3}.

**Characterization**

TEM images and selected area electron diffraction (SAED) patterns were acquired on a Zeiss Libra 120 microscope operating at 120 kV. Energy dispersive X-ray (EDX) spectra were acquired on a JEOL JEM-2200FS high-resolution microscope operating at 200 kV. TEM samples were prepared from the cluster solution in toluene (\textasciitilde 0.5 mg mL\textsuperscript{-1}) on conventional TEM grids (carbon-coated copper grids, 400 mesh, supplied by Quantifoil GmbH). X-ray powder diffraction (XRD) data were acquired on a PANalytical X’pert PRO diffractometer utilizing Cu K\textsubscript{α} radiation. Dynamic light scattering (DLS) was performed on a Malvern ZS90 at a detection angle of 90°. \textsuperscript{1}H NMR spectra of mineral clusters were recorded using CDCl\textsubscript{3} as the solvent on a Bruker AV (500 MHz) spectrometer. UV-vis spectra of mineral clusters and PCDA in hexane were measured on a UV-3150 photospectrometer (Shimadzu, Japan). Attenuated-total-reflection infrared spectroscopy (ATR-FTIR) was conducted on a Perkin Elmer device (Spectrum 100 FTIR, equipped with a diamond ATR crystal). Analytical ultra centrifugation (AUC) was carried out on a Beckman-Coulter XL-I using Rayleigh interference optics and running the sample in self-build Ti double-sector cells at 25 °C. Thermal gravimetric analysis (TGA) was performed on a Netzsch STA 449 F3 by heating from 50 to 900 °C with a heating rate of 10 K min\textsuperscript{-1} under air flow. The matrix-assisted laser desorption/ionization time-of-flight mass (MALDI-TOF MS) spectrum was recorded on a Bruker Microflex MALDI-TOF with z-cyano-4-hydroxycinnamic acid (HCCA) as the matrix and toluene as the solvent. The radial integration of SAED patterns was calculated utilizing software packages, ImageJ 1.50i and JEMS-SAAS. Simulation of XRD curves for nanocrystalline mineral phases (standard CIF files from the ICSD database) was performed using the Reflex Module of Materials Studio 7.0. The crystallite size was set to 1.5 × 1.5 × 1.5 nm\textsuperscript{3}.

**Results and discussion**

For clarity, all the mineral clusters that were successfully synthesized by the gas diffusion method are compiled in Table 1. All the synthesized clusters exhibit an average size between 2.7 and 6.6 nm. To synthesize carbonate-based mineral clusters, typically, 10 mM cation salt (CaCl\textsubscript{2}, MgCl\textsubscript{2}, SrBr\textsubscript{2}, EuCl\textsubscript{3}, TbCl\textsubscript{3}, or CeCl\textsubscript{3}) and 4 mM PCDA were dissolved in ethanol, followed by gas diffusion from (NH\textsubscript{4})\textsubscript{2}CO\textsubscript{3} decomposition for three days. These cation salts were chosen because they show good solubility in ethanol. Released CO\textsubscript{2} serves as a carbonate source and NH\textsubscript{4} renders the solution basic. For calcium phosphate and calcium oxalate, polyphosphoric acid (PPA) and dimethyl oxalate were added into the solution as the sources of phosphate and oxalate from hydrolysis reactions controlled by ammonia diffusion. After thorough washing with repeated precipitation in ethanol and redissolution in toluene to remove any possible impurities, the resultant clusters can be well dispersed in organic solvents like toluene, and are stable without any changes for a long period of time (at least one year, see Fig. S2, ESI† for the XRD profiles of several clusters after long-term storage). Only the solution of Ce\textsubscript{2}(CO\textsubscript{3})\textsubscript{3} clusters is light-yellow, while all the others are transparent.

The key roles of ligand structure and feed ratio have been discussed before in the case of CaCO\textsubscript{3} clusters.\textsuperscript{28} Ethanol is also essential for the formation of mineral clusters, while methanol and isopropanol did not work well (data not shown). Using
ethanol as the solvent not only dissolves PCDA, and metal cations (M\(^+\)) and anions (A\(^-\)), but also promotes the formation of stable amorphous precursors. Ethanol is known to be able to stabilize amorphous phases of minerals like CaCO\(_3\), of stable amorphous precursors. Ethanol is known to be able to

Enlarged TEM images of the clusters can be found in Fig. S1, ESI. \(^{b}\) The data for CaCO\(_3\) clusters were reported in our previous paper,\(^{25}\) and are presented here only for comparison. \(^{c}\) PPA: polyphosphoric acid.
success incorporation of mineral cores inside the PCDA chains. The successful synthesis of mineral clusters is also confirmed by ATR-FTIR spectra of the dried clusters (Fig. S6, ESI†). The O–H stretching band of structural water around 3300 cm⁻¹, C–H stretching bands from PCDA (3000–2780 cm⁻¹), C═O stretching band of COO⁻ from PCDA (1573–1530 cm⁻¹) and two characteristic stretching bands for CO₃²⁻ (ν₂, 870–850 cm⁻¹; ν₃, 1410–1400 cm⁻¹) can be observed, indicating that the deprotonated PCDA binds to the mineral core by chelation. As in the case of CaCO₃, all the mineral clusters have disordered and hydrated cores. The exact hydration and ionic association status is not yet known and needs to be clarified further. Additionally, judging from the size, it is interesting to find that a larger atomic size (Sr > Ca > Mg) and a higher ionic charge (trivalent for Eu³⁺, Tb³⁺, Ce³⁺, divalent for Mg²⁺, Ca²⁺, Sr²⁺) lead to a smaller cluster size, perhaps due to a higher affinity to the carboxylate group in the deprotonated PCDA chains.

CaCO₃, Ca₄(PO₄)ₓ and CaC₂O₄ are important biominerals abundant in animals and plants. For example, Ca₄(PO₄)ₓ in the form of hydroxyapatite is the main component of bone and teeth, and CaC₂O₄ is generated within membrane chambers of specialized cells in higher plants. Again, our method showed good control over the size of Ca₄(PO₄)ₓ and CaC₂O₄, as shown in Fig. 3 (enlarged TEM images are shown in Fig. S1, ESI†). It is noted that for the preparation of dispersible Ca₄(PO₄)ₓ clusters, the hydrolysis of PPA was employed to produce phosphate ions. From the SAED patterns, the two clusters are also amorphous and the signals of Ca and P can be detected by EDX. Similarly, UV-vis and ¹H NMR spectra of Ca₄(PO₄)ₓ clusters (Fig. S3 and 4, ESI†) confirm their core–shell structure. DLS and AUC measurements (Fig. S5 and S7, ESI†) both reveal the rather small size of Ca₄(PO₄)ₓ clusters in solution. IR spectra of Ca₄(PO₄)ₓ and CaC₂O₄ clusters (Fig. S6, ESI†) show the C–H and C═O stretching bands from PCDA and the O–H stretching band from structural water. A few characteristic bands for Ca₄(PO₄)ₓ and CaC₂O₄ can also be observed.

Due to the significant importance of Ca₄(PO₄)ₓ as well as its relatively complex structure involving both PO₄³⁻ and HPO₄²⁻, we performed further thermogravimetric analysis (TGA) and matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF MS) measurements to elucidate its structure, as shown in Fig. 4. In the TGA, as temperature increases, the removal of structural water and PCDA decomposition take place successively. The remaining material at 900 °C may be represented by the formula Ca₁.₅x.₃y(PO₄)ₓ(P₂O₇)ₚ, or present a mixture of Ca₄(PO₄)ₓ and Ca₃P₂O₇. Ca₃P₂O₇ forms upon decomposition of CaHPO₄. To know the exact chemical composition of the Ca₄(PO₄)ₓ cluster, MALDI-TOF MS was recorded, which allows for the assessment of the proportion
of the different species. The largest detected species with a probable formula of (CaHPO₄)₆(H₂O)₄(PCDA)_₄ agrees well with the TGA results and should represent the actual formula of the cluster. It is also noted that the Ca₃(PO₄)₂ core has a stoichiometry similar to amorphous dicalcium phosphate produced in ethanol media.²⁹ This conversely reveals that PCDA stops the nucleation/growth of calcium phosphate in ethanol at a very early stage.

Natural minerals often have a hybrid structure. For example, Mg²⁺ is an important modifier of CaCO₃ morphology and growth, and changes in the Mg/Ca ratio of sea water may have governed the polymorphic transitions of carbonate-based minerals during the geologic past.³⁰ Natural hydroxyapatite in animal bone contains about 4–7 wt% carbonate.³¹ Therefore, to test the ability of our method to stabilize hybrid mineral clusters, we mixed CaCl₂ and MgCl₂ for Ca₂CO₃ test the ability of our method to stabilize hybrid mineral clusters, we compared the radial integration plots of SAED patterns with the simulated XRD curves of their corresponding crystalline phases, as shown in Fig. S8, ESI.³² The size of crystalline phases was set to 1.5 × 1.5 × 1.5 nm³, and thus broad peaks are obtained due to the Bragg peak broadening effect from size reduction. Interestingly, the SAED radial integration curves of the mineral clusters exhibit several peaks that are in similar positions to the simulated XRD curves of corresponding nanocrystalline phases. This reveals that even in such small mineral entities, less than 2 nm, short-range order may already exist like in the case of CaCO₃ clusters as we reported recently.³³ Nevertheless, this still needs to be confirmed by more advanced techniques such as solid-state NMR and X-ray absorption spectroscopy (XAS).

Conclusions

In this paper, we developed a general gas diffusion strategy using PCDA as a ligand and ethanol as a solvent to fabricate stable amorphous mineral clusters with a core size of less than 2 nm. First discovered for CaCO₃, the method was successfully extended to produce monolayer protected clusters of MgCO₃, SrCO₃, Eu₂(CO₃)₃, Tb₂(CO₃)₃, Ce₂(CO₃)₃, Ca₄(PO₄)₆, CaC₂O₄ and their hybrid minerals, CaMg₂(PO₄)₆ and Ca₃(CO₃)₂(PO₄)₂. All the mineral clusters show core–shell structures similar to the CaCO₃ cluster we reported before,³⁴−³⁶ but with different sizes (2.7–6.6 nm) and compositions. The chemical formula of the Ca₃(PO₄)₂ cluster was further confirmed to be (CaHPO₄)₆(H₂O)₄(PCDA)₄. Although we cannot directly link the here presented monolayer protected mineral clusters to pre-nucleation...
clusters,\(^1\) the successful stabilization of such small mineral entities implies that mineral clusters as small as pre-nucleation clusters indeed exist. Our work paves a way for the artificial synthesis of colloidal mineral clusters, which may have various uses in both fundamental research and industry (e.g. as filler nanomaterials or nanocarriers).
