2Department of Migration and Immuno-ecology, Max Planck Institute for Ornithology, Radolfzell 78315, Germany

Summary

1. Determining how events interact across stages of the annual cycle is critical for understanding the factors that affect individual fitness. However, there is currently little information detailing how breeding events influence migratory behaviour.

2. Using an automated digital telemetry array and an isolated island-breeding population of Savannah sparrows Passerculus sandwichensis, we provide the first direct evidence that the timing of breeding events carries over to influence the timing of migration in a songbird and assess for the first time how weather conditions on the breeding grounds also affect departure dates.

3. Date of migratory departure between September and October was strongly influenced by date of breeding completion in adults and fledging date in juveniles from June to July.

4. With respect to weather, adults departed during the first half of high-pressure systems, while juveniles departed throughout the entirety of high-pressure systems (including rainy evenings on the western edge of systems).

5. By combining both ecological and weather data, we could explain almost all variation in departure date for adults (95%), but weather conditions were not a good predictor of departure date for juveniles.

6. Our results provide strong evidence that the timing of breeding events is an important driver of migration timing and that exact departure dates are fine-tuned according to local weather conditions in adults, but not in juveniles.

Key-words: carry-over effects, early-life events, life-history stages, life-history trade-offs, migration, movement, radiotelemetry, songbirds, telemetry array

Introduction

The annual cycle of vertebrates is organized into a series of life-history stages, each characterized by a unique combination of morphological, physiological, and behavioural traits that maximize fitness in response to predictable fluctuations in environmental conditions (e.g. seasonality; Jacobs & Wingfield 2000; Dänhardt & Lindström 2001; Wingfield 2008). Determining how events or processes interact between the stages of the annual cycle is critical for understanding the factors that influence individual fitness and population dynamics (Norris & Marra 2007; Harrison et al. 2011). One common mechanism through which events in one stage carry over to affect individual success in a subsequent stage is through timing, where delays in an earlier stage cause a mismatch between actual and optimal timing in subsequent stages (Harrison et al. 2011). For example, mule deer that delay autumn migration are more likely to experience food shortages en route as a result of deteriorating weather conditions (Monteith et al. 2011), and late migrating monarch butterflies Danaus Plexippus in the spring have increased risk of mortality from high temperatures in Texas and their offspring are less likely to survive (Malcolm, Cockrell & Brower 1987).

In migratory birds, the timing of autumn migration is hypothesized to affect individual survival because late departing individuals may be more likely to encounter inclement weather on the breeding grounds or en route and may experience lower resource availability at stopover sites as a result of resource suppression by earlier migrants (Newton 2006, 2007, 2008). At the broadest temporal scale, timing of migration is controlled by a heritable endogenous circannual rhythm (Berthold 1996; Gwinner & Helm 2003; Gwinner 2008). At a finer scale, correlations between fledging
date and the onset of migratory activity in the laboratory (Pulido et al. 2001; Pulido & Widmer 2005), broad indirect correlations between the average timing of events on the breeding grounds and the average timing of migration at stopover sites for different study populations (Bojarinova, Rymkevich & Smirnov 2002) and correlations between average timing of breeding and average date of last capture measured across years (Morton & Pereyra 1994) suggest departure dates can be modified by an individual’s breeding or natal history. At an even finer temporal scale, studies at stopover sites suggest timing of migration is controlled by the availability of favourable weather conditions for migration (Åkesson & Hedenström 2000; Sapir et al. 2011). However, to date, there has yet to be a direct assessment of how the timing of breeding events and the availability of favourable weather conditions for migration influence the timing of migration from the breeding grounds in free-living songbirds.

Using a digital radiotelemetry array and detailed reproductive information collected over 2 years, we examined how the timing of breeding events influenced the timing of migratory departure in adult and juvenile Savannah sparrows Passerculus sandwichensis inhabiting a small isolated island. We hypothesized that date of migratory departure was dependent on date of breeding completion or fledging date because individuals require a set amount of time following these events to prepare for migration (e.g. to moult; Newton 2008). We predicted a positive relationship between date of migratory departure with both date of breeding completion and fledging date in adults and juveniles, respectively. We also examined the hypothesis that residual variation in date of departure not accounted for by breeding variables, body condition, age or year, could be accounted for by variation in weather. We predicted that individuals departing earlier than expected did so because they encountered favourable conditions for migration and that individuals departing later than expected did so because they encountered unfavourable weather conditions up until the evening they departed.

Materials and methods

STUDY SITE AND SPECIES

Fieldwork was conducted on Kent Island, an isolated 80-ha island in the Bay of Fundy, New Brunswick, Canada (44°35′N, 66°45′W; Fig. 1). We studied a population of migratory Savannah sparrows inhabiting a 10-ha old-field located in the centre of the island. Savannah sparrows are grassland songbirds that breed in the northern United States and across Canada, and primarily winter throughout the southern United States (Wheelwright & Rising 2008). On Kent Island, median clutch size is four eggs (Wheelwright & Schultz 1994), and median adult body mass during the breeding period is 20 g for males and 19 g for females (Freeman-Gallant 1996). Adults typically begin breeding in late May and fledging generally occurs 26 days after the first egg is laid (Wheelwright & Rising 2008).

Savanna sparrows on Kent Island represent an ideal population to examine the links between the breeding period and autumn migration for two main reasons. First, variation in the number of clutches per season and moderate nest predation rates resulted in a range of fledging dates (Wheelwright & Rising 2008). Second, the small size of the island and its isolation restricted the scope of pre-migratory movements and allowed us to be confident that departures from the island represented initial migratory movements.

BREEDING PERIOD

Nests were located between 30 May and 25 July in 2009 and 2010 by observing adult females during the nest-building and incubation stages. Unbanded adults were captured on their breeding territories with mist-nets and subsequently banded. At the time of capture, tarsus length (±1 mm) was measured according to Pyle (1997), and a top-loading electronic balance was used to measure mass (±0.1 g). Sex was assigned based on the presence or absence of a brood patch or cloacal protuberance and was later confirmed with observations of breeding behaviour (e.g. singing males, incubating females, copulation and mate-guarding). Timing of breeding completion was calculated as the fledging date of the last nest in a season + 14 days, which represents the average time until parental independence (Wheelwright & Rising 2008). In the event that an individual’s last nest attempt failed (n = 5), we defined date of breeding completion as the last day for which the nest was known to be active (nests were visited every 2 days to monitor nest fate). Nestlings were banded at 7 days of age, and banding date was used as an index of fledging date (which normally occurs 9–11 days following hatch; Wheelwright & Rising 2008). Tarsus length and mass were measured as described earlier.

PRE-MIGRATORY PERIOD

Individuals were captured between 01 September and 25 October in 2009 and between 18 August and 20 October in 2010. Each day
between 07.00 and 17.00 h AST, 2–3 50 × 50 m quadrants were randomly selected (from 29 in total) without replacement for netting. Upon capture, the same morphological measurements described earlier were taken, and individuals were fitted with small digitally coded radiotransmitters (0.9 g, 62 days minimum battery life; model NTQB-3-2, Lotek, Newmarket, ON, Canada).

Radiotransmitters were deployed between 1 September and 9 October in 2009 and between 25 August and 29 September in 2010. In both years, the majority of transmitters were deployed prior to 15 September (37 of 42 or 88% of transmitters deployed in 2009 and 47 of 55 or 85% of transmitters deployed in 2010). In 2009, 24 adults and 18 juveniles were fitted with radiotransmitters and in 2010, 26 adults and 29 juveniles were fitted with radiotransmitters. Transmitters were affixed to birds using a figure-eight leg-loop harness (Rappole & Tipton 1991) comprised of elastic thread (mass of harness + adhesive for attachment = 0.08 g; total mass of radio + harness = 0.70 g). In a recent analysis on the same population, we showed that radiotransmitters had no effect on total body water or the quantity of fat for adults or juveniles during the pre-migratory period (Rae et al. 2009).

**DEPARTURE DATE**

Date of departure was measured using an automated digital telemetry array comprised of three 9-m towers (Fig. 1) affixed with four 4-element Yagi antennas. Because radiotransmitters were digitally coded, we assigned all transmitters to one of three VHF radio frequencies. Our scanning cycle ensured that each individual was monitored continuously for 21.6 s in 64.8-s intervals. Please refer to Supporting Information: Appendix S1 for a detailed description of our telemetry methods, Appendix S2 for detailed predictions regarding age, sex, year, and body condition, and Appendix S3 for a summary of the methods used to estimate body condition at departure.

**WEATHER**

Surface wind direction (direction form which winds were blowing relative to geographic north in 10° intervals), surface wind speed (km h⁻¹) and atmospheric pressure (kPa) were measured hourly at the Grand Manan Weather Station (45°19′05″0″N 65°53′06″1″W; 110 km north-east of Grand Manan), and were again accessed from the Canadian National Climate Information and Data Archive (NCIDA; http://www.climate.weatheroffice.gc.ca, accessed 25 January 2012). Precipitation (raining or not raining), cloudiness (1 = clear skies, 2 = 1/10th to 4/10ths cloud cover, 3 = 5/10ths to 9/10ths cloud cover, 4 = overcast) and visibility (max = 241 km) were also collected hourly, but from the Saint John Airport Weather Station (45°19′05″0″N 64°48′06″9″W; 136 km north-west of Kent Island) and were accessed from the NCIDA. Given that meteorological measurements were collected every hour, all data were measured within at least half an hour of each departure. See Appendix S4 for detailed predictions related to weather variables.

**STATISTICAL MODELS**

All analyses were conducted in R version 2.12.1 (R Development Core Team 2008). For adults, date of departure was modelled using a multiple linear regression model (stats-package; R Development Core Team 2008). Two adults were measured in both years of the study. Exclusion of one randomly selected departure date for each of these individuals did not affect the sign, magnitude or significance of parameter estimates (Table S1), and so all departure dates were retained in the analysed dataset. For juveniles, date of departure was initially modelled using a linear-mixed effects model (nlme-package; Pinheiro et al. 2010) with restricted maximum likelihood estimates of parameter coefficients because we measured departure dates for 12 groups of siblings. Random effects were included for natal nest nested within mother ID to control for covariances among nest mates and siblings; however, a likelihood ratio test indicated that the random effect for natal nest was not significant (χ² = 1.3, P = 0.248), and a restricted likelihood ratio test (RLRsim package; Scheipl 2010) indicated that the random effect for natal nest was also not significant (P = 0.217). Thus, for parsimony, both random effects were removed from the final model.

Likelihood of departure with respect to weather was modelled using conditional logistic regression models (survival-package; Therneau & Lumley 2011), which are ideal for situations where the choice set (what is available) varies between individuals (Manly et al. 2002). In our models, the choice set was defined by the residuals from the departure date models. For example, if a bird was predicted to depart on the evening of day 200 but actually departed on the evening of day 206, then this bird’s choice set would be the evenings of days 200 through 206. Weather variables for days when birds did not depart were measured at 2.1 h following sunset for adults and 2.4 h following sunset for juveniles. These values represent the median times of departure during the evening for each age group. Again, removal of one randomly selected departure date from each of the two adults that were tracked in both years of the study had little effect on the sign, magnitude or significance of parameter estimates (Table S2). For juveniles, random effects were specified for nest ID and mother ID. In the event that the predicted date of departure was the same as the actual date, the choice set was defined by the departure day and the day immediately preceding departure.

To determine whether the unexplained variation from our departure date models could be accounted for by weather, we used a two-step procedure. First, we assigned a likelihood of departure to each evening in each bird’s choice set using our conditional logistic regression models. The evening with the highest likelihood of departure represented our new estimate of departure date. We then regressed these estimates on the observed departure dates to obtain a new R² value. Second, we used a bootstrap procedure to evaluate the significance of the R² values from step one. Specifically, we regressed observed departure dates on randomly chosen departure dates from each bird’s choice set and repeated this procedure 10,000 times. This allowed us to assess the probability of obtaining an R² value as high or higher than the R² value obtained after accounting for weather.

Significance of parameter estimates and statistical tests for all analyses were evaluated at α = 0.05. Potential curvilinear relationships were assessed prior to model fitting using scatter-plots fitted with loess lines for the linear models and plots of the 25% quantile midpoints for each predictor vs. the predicted logit values for the conditional logistic regression models (Hosmer & Lemeshow 2000). Correlations between predictors were evaluated through the variance–covariance matrix of the fitted models (r ≥ 0.7 were considered to be highly correlated). Model fit was visually assessed using residual plots. Unless otherwise stated, reported results are for standardized data.

**Results**

**DEPARTURE DATE**

The average date of breeding completion for adults was 23 July (SD = 13 days) in 2009 and 27 July (SD = 9 days) in
2010. Average fledging date for juveniles was 09 July in both years (2009: SD = 14 days; 2010: SD = 11 days). The average amount of time between when an adult was last captured and when they departed on migration was 17 days (SD = 8) in both 2009 and 2010. Adults departed an average of 77 days (SD = 12) following breeding completion in 2009, and 67 days (SD = 6) following breeding completion in 2010. Average date of departure for adults was 4 October (SD = 11 days; range = 15 September–29 October) in 2009 and 8 October (SD = 7 days; range = 11 September–14 October) in 2010. Juveniles departed an average of 88 days (SD = 15) following fledging in 2009 and 78 days (SD = 12) following fledging in 2010. Average date of departure for juveniles was 7 October (SD = 11 days; range = 16 September–27 October) in 2009 and 27 September (SD = 11 days; range = 12 September–25 October) in 2010. Adults departed significantly later than juveniles in 2010 (t-test: \( t_{46} = -2.5, P = 0.015 \)), but not in 2009 (t-test; \( t_{57} = 0.5, P = 0.638 \)).

**ECOLOGICAL AND LIFE-HISTORY PREDICTORS OF DEPARTURE**

As predicted for adults, date of departure was positively correlated with date of breeding completion (\( \beta = 0.57, t_{44} = 6.0, P = <0.001; \) Fig. 2a, Table 1) and age (\( \beta = 0.35, t_{44} = 3.9, P = <0.001 \)), and varied between years, being earlier in 2010 relative to 2009 (difference of mean departure date = 4.6 days; \( \beta = -0.62, t_{44} = -3.3, P = 0.002 \)). Opposite to our prediction, females left significantly earlier than males (difference of mean departure date = 5.5 days; \( \beta = 0.68, t_{44} = 3.3, P = 0.002 \)). We found only weak evidence for an effect of body condition on date of departure (\( \beta = 0.19, t_{44} = 1.8, P = 0.082; \) Fig. S2a). Together, our departure date model accounted for 67% of the observed variation in timing of departure for adults.

As predicted for juveniles, date of departure was positively correlated with fledging date (\( \beta = 0.22, t_{43} = 2.1, P = 0.040 \); Fig. 2b, Table 1) and body condition (\( \beta = 0.57, t_{43} = 5.3, P = <0.001; \) Fig. S2b). Similar to adults, date of departure was earlier in 2010 relative to 2009 (\( \beta = -0.57, t_{43} = -2.7, P = 0.010 \)). Together, the main effects from our departure date model accounted for approximately 56% of the observed variation in timing of departure for juveniles.

**WEATHER PREDICTORS OF DEPARTURE**

As predicted, adults departed under clear weather conditions: no precipitation and maximum visibility (50 of 50 observations; Fig. 3a,b) and were more likely to depart when air pressure was high (\( \beta = 1.60, z = 3.0, P = 0.003 \); Table 2) and increasing (\( \beta = 3.75, z = 3.5, P = 0.001 \)). We did not find strong support for an interaction between surface wind speed and direction (Table S3); however, likelihood of departure did vary with wind direction independently of wind speed; adults were less likely to depart if winds were blowing from the south as opposed to winds from the north-east (\( \beta = -3.24, z = -2.4, P = 0.017 \)), but individuals were no more or less likely to depart when winds were blowing from north-east relative to the north-west (\( \beta = 0.80, z = 1.2, P = 0.247 \)). In general, adults were more likely to depart under low wind conditions, but on one occasion, four individuals chose to depart under very high wind conditions (\( >45 \text{ km h}^{-1} \); Fig. 3a). This latter group of individuals resulted in a significant convex curvilinear relationship between likelihood of departure and surface wind speed (linear term for wind speed: \( \beta = -1.32, z = -2.6, \)}
Parameter estimates are for un-standardized data.

P = 0.010; curvilinear term for wind speed: β = 0.49, z = 3.1, P = 0.002. We also found weak evidence for an interaction between surface wind speed and date, where individuals became increasingly less likely to depart under high wind conditions as date progressed (β = -1.00, z = -1.8, P = 0.070). Last, and opposite to our prediction, controlling for all other main and interaction effects, individuals were more likely to depart as cloud cover increased (β = 2.78, z = 2.8, P = 0.005); however, cloud cover was fairly strongly correlated with decreases in pressure (r = 0.67), and when the effect of cloud cover is modelled on its own, the sign of the effect is in the predicted direction (β = 0.96, z = -2.6, P = 0.010); therefore, this result should be interpreted with caution. Together, the main effects in our weather model for adults accounted for 65% of the observed variation in the likelihood of departure.

Fig. 3. Weather variables used and avoided in (a) 2009 and (b) 2010. Panels represent (from top to bottom), wind speed (km h⁻¹), atmospheric pressure (kPa), and presence or absence of precipitation 2 h following sunset, as well as the total number of juveniles and adults departing each evening. In the bottom two panels, each circle represents one individual. The ordinal dates of 253 and 301 represent 11 September and 29 October, respectively.

Juveniles were much less choosey about weather conditions during departure than adults. Unlike adults, juveniles departed under rainy conditions (seven of 47 individuals; Fig. 3a,b), when visibility was less than maximum (11 individuals) and when winds were blowing from the south (17 individuals; Fig. 1). However, despite observations of some individuals departing in the rain, overall, juveniles tended to avoid departing during rainy evenings (β = 1.96, z = -2.2, P = 0.028; Table 2). Similar to adults, we did not find strong evidence for an interaction between surface wind speed and direction (Table S3), individuals did not prefer winds from the north-east relative to the north-west (main effect: β = 1.37, z = 1.8, P = 0.068; interaction effect with date: β = 0.68, z = 0.8, P = 0.426), and juveniles were more likely to depart when atmospheric pressure was high (β = 0.91, z = 2.0, P = 0.050). However, different from adults, juveniles readily departed when winds were blowing from the south and the strength of this effect increased with departure date (main effect for winds from south-west: β = 1.17, z = 1.7, P = 0.092; interaction effect with date: β = 1.48, z = 2.3, P = 0.002; main effect for winds from south-east: β = -1.13, z = -1.7, P = 0.090; interaction effect with date: β = 5.59, z = 3.1, P = 0.002), individuals did not respond to changes in atmospheric pressure (β = -0.09, z = -0.19, P = 0.847), there was no effect of wind speed on likelihood of departure (linear term for wind

Parameter estimates are for un-standardized data. "$\beta$" refers to curvilinear term and "X" indicates an interaction. Note: a main effect for date cannot be estimated because this variable is constant across an individual’s choice set (referred to as a matching variable: Hosmer & Lemeshow 2000).

Combining Ecological and Weather Data

The $R^2$ value for the regression of observed dates of departure with predicted dates of departure after having accounted for weather for adults was 95% (Fig. 4a). Our bootstrapping procedure indicated that an $R^2$ value greater or equal to this was extremely unlikely by chance ($P < 0.001$; three of 10,000 iterations; Fig. 4a: inset). For juveniles, the $R^2$ value for the regression of observed dates of departure with predicted dates of departure after having accounted for weather was 89% (Fig. 4b), but different from adults, a value greater or equal to this was not statistically different from what we would expect had we randomly chosen a departure day in each individual’s choice set ($P = 0.181$; 1810 of 10,000 iterations; Fig. 4b: inset).

Discussion

We provide the first direct evidence that the timing of events on the breeding grounds carries over to affect the timing of autumn migration in both free-living adult and juvenile songbirds. While previous studies on captive birds (Pulido et al. 2001; Gwinner & Helm 2003; Pulido & Widmer 2005; Gwinner 2008) provide evidence for a relationship between the timing of migration and the timing of breeding, they do not include environmental variability (e.g. weather conditions, resource abundance, etc.) that could potentially mask any relationship under natural conditions. Moreover, field studies investigating the relationship between the timing of breeding events and the timing of migration have used indirect methods to measure timing, primarily at stopover sites (Ellegren 1990; Sokolov 2000; Bojarinova, Rymkevich & Smirnov 2002). Specifically, individuals captured at the stopover sites were not the same individuals for which breeding was monitored and relationships were assessed across years, meaning that individual decisions or circumstances involving the timing of events during the breeding period cannot be directly related to the timing of migration. In contrast, our approach using detailed breeding and natal histories and automated tracking methods provides strong evidence that the timing of breeding events influences date of departure in a wild population.

To our knowledge, only one other study to date has attempted to relate the timing of breeding events to the timing of migration in individual songbirds with known breeding and natal histories. Morton & Pereyra (1994) used fat scores and date of last capture at a trap-line to estimate departure date. However, in contrast with our results, evidence for a relationship between fledging date and departure date was not found, and low sample sizes did not allow for an assessment of the relationship between date of departure and date of breeding completion. Also, passive capture methods...
generally underestimate departure dates and add noise to analyses (Schaub et al. 2001), which might partly explain why a relationship between fledging date and timing of migration was not found. Alternatively, departure from the study site may not have reflected migration, but instead, broad-scale pre-migratory movements (Vega Rivera et al. 1998). In contrast, by measuring departure directly from an isolated island, we can be confident that departures represent migratory departures and we avoid any issues with sample sizes and bias associated with passive capture methods.

Life-history theory predicts trade-offs between time and energy invested in breeding and subsequent survival. To date, several studies have identified negative correlations between survival and date of breeding completion in adults (Nilsson & Svensson 1996; Hemborg 1999), and between first-year survival and fledging date in juveniles (Møller 1994; Shutler et al. 2006; Mitchell et al. 2011). We suggest that delayed departure represents a proximate mechanism linking the timing of events during breeding with annual survival. Specifically, late departing individuals may experience increasingly inclement weather on the breeding grounds or during migration, and may experience diminished resources at stopover sites owing to suppression by earlier migrants (reviewed by Newton 2006, 2008). Because migration is energetically demanding (Wikelski et al. 2003; Bowlin, Cochran & Wikelski 2005), increased energy expenditure or decreases in resource intake may result in increased mortality en route (Newton 2006, 2007).

We observed females departing before males, and in one year, juveniles departing before adults. This is the first direct evidence for differential timing of migration from the breeding grounds among sex and age classes in a migratory songbird. Several hypotheses may account for these patterns. Differences in timing may reflect differences in the ability of individuals to cope with poor weather in the fall. In our population, males are larger than females, and adults are larger juveniles (Wheelwright & Rising 2008), thus, smaller birds may depart earlier because they are less able to cope with poor weather (Ketterson & Nolan 1976; Brown & Brown 1998). Differences in timing might also reflect differences in competitive ability on the breeding grounds or at stopover sites (Terrill 1987), if, for example, males can outcompete females and if adults can outcompete juveniles (Ketterson 1979; Piper & Wiley 1989). This hypothesis is also supported by our observation of younger adults departing before older adults, as adult age can also be positively correlated with social dominance (Piper & Wiley 1989). Alternatively, differences in the timing of departure may reflect differences in wintering latitude between age and sex classes (Ketterson & Nolan 1976). For example, males might leave later than females and adults after juveniles if they do not need to migrate as far to their wintering grounds. Last, differences in timing between age groups may reflect differences in the duration of moult (Newton 2008); juveniles are only moulting their body feathers, while adults are replacing body and flight feathers, suggesting that departure dates for adults might be constrained by the completion of moult. However, this mechanism cannot be invoked to explain differences in timing between sexes, as moult schedules are similar in each sex (Mitchell et al. 2012).

We found a positive relationship between our estimate of condition at departure and timing of migration in juveniles, suggesting that juveniles leaving early are in lower body condition than juveniles departing later in the season. A similar pattern between condition and timing of migration has been found in several other species at stopover sites – late migrating individuals have greater fat reserves (Ellegren 1991; Bairlein 1998; Izhaki & Maitav 1998; Hedenström 2004). Whether this pattern reflects greater migration distances for

**Fig. 4.** Regression of actual departure dates on predicted departure dates for (a) adults and (b) juveniles. Inset histograms: probability distributions for $R^2$ values when departure dates are randomly selected from each individual’s choice set (10 000 iterations). Hatched line in each inset histogram represents the $R^2$ value from the regression between observed departure dates and those predicted after accounting for breeding or natal history and weather.
late departing individuals, selection for greater migration speeds late in the season (sensu Newton 2008; although see Bairlein 2001), an insurance policy against increasingly inclement conditions, or is simply an artefact of having more time to accumulate fat reserves on the breeding grounds prior to departure has not been explicitly tested. Regardless, it suggests that overall migration speed will be faster for late departing juveniles, as they will likely have to stopover less frequently or for shorter durations while refuelling (Wikelski et al. 2003; Newton 2008).

Departure date of songbirds from the breeding grounds may be controlled by several proximate mechanisms operating at different temporal scales. At the broadest scale, evidence suggests that the timing of migration is controlled by a heritable endogenous mechanism (Pulido et al. 2001; Gwinner & Helm 2003; Pulido & Widmer 2005; Gwinner 2008). At a slightly finer scale, life-history decisions for adults and early-life circumstances for juveniles may determine the approximate time an individual will be ready to depart. At the finest scale, the availability of favourable weather conditions for migration may determine exact departure dates from the breeding grounds. In accordance with this general framework, we found that the variance in date of departure that could not be accounted for by individual life histories could be almost entirely accounted for by weather in adults, but not juveniles. Departure during favourable weather may have many benefits, such as reduced energy expenditure, increased migration rate and reduced mortality risk (Richardson 1978; Alerstam 1979; Liechti & Bruderer 1998; Bowlin & Wikelski 2008). It is therefore curious that juveniles depart under what appear to be relatively poor weather conditions and suggests migration under such conditions is not costly in Savannah sparrows, juveniles are able to mitigate any adverse negative effects or migration under poor weather conditions is less costly then remaining on the breeding grounds.

During their first autumn migration, juvenile migrants of many species have been shown to rely on different orientation mechanisms and to have less developed navigational abilities relative to adults (e.g. Thorup et al. 2003, 2007). It follows then, that adults and juveniles may use a different set of rules when selecting weather conditions for departure. We found that adults were much more choosy about certain weather conditions relative to juveniles. Adults but not juveniles avoided winds with any southerly component and did not depart during rainy evenings or when visibility was low. These differences may reflect adults choosing to depart only during the onset and up to the middle of high-pressure systems (light winds from the north, high and increasing pressure), while juveniles were choosing to depart throughout high-pressure systems, including the backside of the high-pressure systems as warm fronts were approaching (light to moderate southerly winds, precipitation; Richardson 1978; Cochrán & Wikelski 2005). This would explain why we observed seven juveniles departing under rainy conditions, why juveniles were departing with southerly winds, why juveniles did not respond to changes in atmospheric pressure and why departure dates for juveniles were less clumped in time relative to adult departures.

Our results also suggest that juveniles were more willing to take risks later in the season relative to adults. Specifically, juveniles were more likely to depart when winds were blowing from the south (poor weather; see above) as date progressed, again suggesting that the costs of departing under unfavourable weather conditions outweigh the costs of remaining on the breeding grounds or that late departing individuals are better able to mitigate the costs of doing so (e.g. late departing juveniles are fatter and may be better able to mitigate any energetic cost of flying into a head wind). In contrast, adults appeared to become more choosy later in the pre-migratory period with respect to wind; individuals were less likely to depart as wind speed increased later in the season. If the risk of being blown off course increases with wind strength, perhaps greater time constraints late in the fall make it difficult to mitigate additional delays or energy expenditure associated with being blown off course.

The organization of the annual cycle of migratory vertebrates suggests that life-history trade-offs or circumstances affecting the timing of events in one life-history stage (sensu Jacobs & Wingfield 2000; Wingfield 2008) may carry over and influence individual success in subsequent life-history stages. This is because the timing of each stage is relatively inflexible (Wingfield 2008), and as result, individuals have little time to mitigate effects from previous life-history stages. Our results support this hypothesis by illustrating a strong relationship between date of migratory departure with both date of breeding completion and fledging date in a free-living migratory songbird.
