The Role of Norepinephrine and α-Adrenergic Receptors in Acute Stress-Induced Changes in Granulocytes and Monocytes

Daniel Beis, PhD, Roland von Känel, MD, Nadja Heimgartner, MS, Claudia Zuccarella-Hackl, PhD, Alexander Bürkle, MD, Ulrike Ehlert, PhD, and Petra H. Wirtz, PhD

ABSTRACT

Objective: Acute stress induces redistribution of circulating leukocytes in humans. Although effects on lymphocytes as adaptive immune cells are well understood, the mechanisms underlying stress effects on granulocytes and monocytes as innate immune blood cells are still elusive. We investigated whether the stress hormone norepinephrine (NE) and α-adrenergic receptors (α-ADRs) may play a mediating role.

Methods: In a stress study, we cross-sectionally tested 44 healthy men for associations between stress-induced NE increases and simultaneous granulocyte and monocyte cell count increases, as measured immediately before and several times after the Trier Social Stress Test. In a subsequent infusion study, 21 healthy men participated in three different experimental trials with sequential infusions of 1- and 15-minute duration with varying substances (saline as placebo, the nonspecific α-ADR blocker phentolamine [2.5 mg/min], and NE [5 µg/min]): trial 1 = saline+saline, trial 2 = saline+NE, trial 3 = phentolamine+NE. Granulocyte and monocyte cell numbers were assessed before, immediately after, 10 minutes, and 30 minutes after infusion procedures.

Results: In the stress study, higher NE related to higher neutrophil stress changes (β = .31, p = .045, R² change = .09), but not epinephrine stress changes. In the infusion study, saline+NE induced significant increases in neutrophil (F(3/60) = 43.50, p < .001, η² = .69) and monocyte (F(3/60) = 18.56, p < .001, η² = .48) numbers compared with saline+saline. With phentolamine+NE, neutrophil (F(3/60) = 14.41, p < .001, η² = .42) and monocyte counts (F(2.23/44.6) = 4.32, p = .016, η² = .18) remained increased compared with saline+saline but were lower compared with saline+NE (neutrophils: F(3/60) = 19.55, p < .001, η² = .494, monocytes: F(3/60) = 2.54, p = .065, η² = .11) indicating partial mediation by α-ADRs. Trials did not differ in eosinophil and basophil count reactivity.

Conclusions: Our findings suggest that NE-induced immediate increases in neutrophil and monocyte numbers resemble psychosocial stress effects and can be reduced by blockade of α-ADRs.

Key words: Alpha-adrenergic receptor blocker, granulocytes, monocytes, norepinephrine, phentolamine, stress.

INTRODUCTION

Acute psychosocial stress induces a variety of physiological reactions preparing an organism to perform fight-or-flight reactions and to cope with potential consequences, such as injuries and related tissue damage (1). Physiological stress reactivity comprises activation of the two main stress axes: the first-wave (or immediate) sympathetic adrenomedullary (SAM) system with release of its stress hormones epinephrine (EPI) and norepinephrine (NE), and the second-wave (or delayed) hypothalamus-pituitary-adenal (HPA) axis (1). Stress-responsive physiological reactions that prepare an organism to cope with potential tissue damage and related infections range from increased procoagulant activity (2) to immune system activation, including leukocyte redistribution (3). A variety of studies clearly demonstrate that acute stress induces the redistribution of lymphocytes as blood cells of the adaptive immune system (4–6). So far, studies investigating stress-responses of innate immune cells and underlying mechanisms have extensively focused on natural killer cells (7–9), whereas comparably little is known about other innate immune cells.

Prevalent blood cells of the innate immune system’s immediate and unspecific defenses comprise monocytes and granulocytes having the following three subtypes: neutrophil, eosinophil, and basophil granulocytes. Studies investigating acute psychosocial stress effects on these innate myeloid immune cells in healthy

participants most consistently report transient immediate increases, particularly in monocyte and neutrophil numbers (10–17). Some studies still found increases in monocyte (13,16) and granulocyte (13,18,19) numbers 10 to 15 minutes after stress cessation, whereas most studies failed to detect monocyte (10,11,18–20) and granulocyte (10,11,20) increases at this and later time points up to 120 minutes (10,11,19–21). From an evolutionary “fight-flight” perspective, an acute stress-situation (e.g., imagine a hunter trying to kill a dangerous animal) implicated the risk of being injured. According to this, acute stress-induced transient immediate increases in circulating numbers of monocytes and neutrophils in particular may represent an evolutionary founded reaction that prepares for potential tissue damage and related infection. The main effector functions of monocytes and granulocytes are crucial for survival and include the phagocytosis of pathogens, antigen presentation, and the production and release of different mediators such as cytokines. The latter coordinate subsequent immune reactions but also regulate reactive oxygen species and proteolytic enzymes that disintegrate tissue surfaces (22–25). In the context of repeated or chronic stress, however, repetitive activation of the innate immune response with sustained cytokine production may no longer be adaptive. Based on the model of allostatic load (26), it can indeed give rise to a systemic low-grade inflammatory state with many adverse health consequences, including cardiovascular disease (e.g., (27)).

Hitherto, the mechanisms underlying immediate acute stress-induced increases in monocyte and granulocyte cell numbers are not fully understood. There is evidence that catecholamine release may play a mediating role. On the one hand, EPI and NE increases after stress and monocyte and granulocyte increases reach the same time, i.e., immediately after stress (e.g., (10,17,28)). However, cross-sectional studies that relate stress-induced catecholamine release and monocyte/granulocyte cell count changes are scarce. To the best of our knowledge, only one cross-sectional study investigated associations in women between plasma EPI levels and granulocyte counts in reaction to a speech task at peak reactivity, i.e., immediately after stress, and found a positive correlation (29). On the other hand, infusion studies consistently demonstrate immediate granulocyte (in particular neutrophil) and/or monocyte increases in reaction to infusion or injection of either EPI (30–35) or NE in humans (30,36). It is important to note that in vivo infusion of EPI can dose-dependently induce increases of both EPI and NE (7,35,37), whereas NE infusion increases NE only (7,38). Thus, it is possible that the observed cell increases after EPI infusion are (co)-induced by NE. Notably, infusion duration in these studies ranged from 30 minutes to 2 hours. This was more than twice as long as typical stress tests and the total amount of substance infused was within the supraphysiologic range (30,31,36) applied in all NE and most EPI infusion studies. As yet, there is a lack of infusion studies applying a design that mimics reactivity to typical standardized psychological stress tests in terms of both infusion dosage and duration. The receptor mechanisms for catecholamine-induced redistribution of monocytes and granulocytes are not clear either. NE and EPI have different affinities to α- and β-adrenergic receptors (ADRs (39)). So far, most studies investigated β-ADR mechanisms and in sum found β-ADR to play a partial role, but to not account for full mediation of monocyte and granulocyte cell number increases (for details see Supplementary Text, Supplemental Digital Content 1, http://links.lww.com/PSYMED/A492). Here, the involvement of α-ADR is a likely explanation. Human studies investigating α-ADR mechanisms are lacking, but two animal studies suggest a mediating role at least for granulocyte increases: acute α-ADR blockade by phentolamine neutralized NE-infusion-induced splenic granulocyte release in guinea pigs (40). Likewise, 12-hour pretreatment with phentolamine prevented rats from social defeat stress and induced increases in circulating and splenic granulocytes, but failed to inhibit stress-induced monocyte increases (41).

Taken together, evidence suggests that catecholamines are involved in the mediation of stress-induced transient increases in innate immune blood cell numbers, especially of granulocytes. However, with respect to underlying mechanisms, the specific roles of the catecholamine NE and α-ADR (42,43) remain unclear, particularly in humans.

In this study, we examined for the first time in healthy men cross-sectional associations of stress-induced NE and EPI increases with increases in granulocyte and monocyte counts. Because we found the stress-induced NE increase to relate to neutrophil increases, we further investigated causality of this finding with a placebo-controlled in vivo infusion experiment. We infused in healthy men a dosage of NE that mimics NE-stress reactivity effects in terms of blood pressure (BP) increases as typically observed in reaction to standardized stress induction by the widely used Trier Social Stress Test (TSST (38,44,45)). The infusion duration corresponded to that of the TSST and NE infusion was performed with and without preceding specific α-ADR blockade by phentolamine to identify a potential involvement of α-ADR mechanisms. We hypothesized that stress-induced catecholamine increases would relate to simultaneous innate immune cell count increases, in particular of neutrophils, and that our NE infusion would induce transient immediate increases in monocyte and neutrophil counts. Furthermore, that previous phentolamine application would reduce these increases.

METHODS
Participants

Here, we present data from two in vivo studies in humans, a stress study and a subsequent infusion study. Both studies were parts of larger projects and, in addition to participants’ characteristics, the catecholamine data of both studies, as well as verification of successful phentolamine administration of the infusion study, were previously reported (38,46).

Participants of both studies comprised medication-free, nonsmoking healthy white men aged between 21 and 66 years. We recruited men to rule out potential confounding influences by the menstrual cycle (47–49). Specific exclusion criteria were verified by telephone screening (stress study) or a medical interview (infusion study) and included the following: smoking; any regular or acute medication intake; illicit drug abuse; psychiatric disorders; any heart disease, varicosis or thrombotic diseases; metabolic (e.g., diabetes, elevated cholesterol levels), liver, renal, or pulmonary diseases; rheumatic diseases; cancer; allergies and atopic diathesis; HIV-infection; and any current infections. All participants provided written informed consent before the study began. Both studies were carried out in accordance with the Declaration of Helsinki principles and were approved by the ethics committees of the Cantons of Zurich (stress study) and Bern (infusion study), respectively. The Swiss Agency for Therapeutic Products (Swissmedic) formally approved the research protocol of the infusion study. Participants of the infusion study were compensated
with 120 CHF per day (360 CHF for all 3 days), and participants of the stress study were paid 80 CHF.

The stress study comprised 44 participants with complete blood count data (data collection from April until October 2004) who were recruited through advertisement at the University of Zurich and with the help of the Swiss Red Cross (Zurich). Participants of the infusion study were recruited with the aid of the Swiss Red Cross (Bern) and the Clinical Investigation Unit of the University Hospital of Bern (Inselspital). Twenty-one normo- tensive participants with complete blood count data finished all three trials of the infusion study with a fully balanced trial sequence, rendering a total of 63 trials (data collection from August 2009 to May 2012).

Design and Procedure

Stress Study

In the first study, participants were instructed to avoid alcohol, caffeinated beverages, and strenuous physical exercise as from the evening before reporting to our laboratory at the University of Zurich between 02:00 PM and 04:00 PM. After catheter insertion into the brachial vein of the nondominant arm, followed by a 45-minute resting interval in a quiet room, acute psychosocial stress was induced using the standard protocol of the TSST (44). After a short introduction, participants underwent a 5-minute preparation phase followed by a 5-minute mock job interview and a 5-minute mental arithmetic task in front of a video camera and a committee. After the TSST, participants remained seated in a quiet room. Blood samples were collected immediately before participants were introduced to the TSST, immediately after completion of the TSST, as well as 20 and 60 minutes afterward.

Infusion Study

The infusion protocol is based on the 15-minute TSST paradigm and aims to investigate effects of a NE infusion. It was designed to mimic NE-stress reactivity with and without α-adrenergic blockade. The study was performed at the Clinical Investigation Unit of the Bern University Hospital (Inselspital). In a single-blind, placebo-controlled, within-subject design, all participants took part in three different experimental trials varying in terms of the combination of two sequentially infused substances as previously described (38). These were saline+saline in trial 1, saline+NE in trial 2, and phentolamine+NE in trial 3. Trial 1 was the placebo condition and was performed to control for potential effects of the infusion procedure per se. Trial 2 was the main experimental trial designed to test for the effects of NE infusion. Trial 3 tested whether potential NE effects would be modulated by α1- and α2-ADR-blocker, as phentolamine is a nonspecific α-ADR blocking compound.

The trial sequence was fully counterbalanced by using a Latin Square design with the sequences: 1, 2, 3 (i.e., infusion day 1 was trial 1, infusion day 2 was trial 2, infusion day 3 was trial 3); 2, 3, 1 (i.e., infusion day 1 was trial 2, infusion day 2 was trial 3, infusion day 3 was trial 1); 3, 1, 2 (i.e., infusion day 1 was trial 3, infusion day 2 was trial 1, and infusion day 3 was trial 2). Trials took place on separate days with intertrial intervals of at least 1 to 2 weeks, to allow for phentolamine washout. Ethical and safety considerations regarding potential (hemodynamic) side effects of study substances prohibited a double-blind design. Therefore, the participants, but not the experimenters, were blind to trial substances. All infusions were performed by a board-certified intensivist.

Similar to the stress study, participants abstained from alcohol and caffeinated beverages as from the evening before the test day. Moreover, they abstained from physical exercise for 24 hours and maintained a regular sleep-wake rhythm during the three nights before each trial, with lights out between 10:30 PM and 12:00 MD and lights on between 07:00 AM and 09:00 AM. Participants reported to the laboratory at 11:45 AM to receive a standardized meal with experimental procedures starting at 01:00 PM. Participants were tested in supine position lying on a bed. Each trial started with a 10-minute introduction phase during which the testing procedure was explained, followed by catheter insertion into the brachial vein of the dominant arm for the infusions. For blood sampling, a second catheter was inserted into the brachial vein of the nondominant-arm. After a further 45-minute interval to acclimatize, the infusion procedure started.

For the assessment of blood cell counts, we focused on the fast kinetics of the acute blood cell response identified in the stress study and collected blood samples immediately before the first infusion (baseline), as well as 1, 10, and 30 minutes after the infusion procedure ended. Blood samples for NE and EPI assessments were taken at baseline before the first infusion and 1 minute after the second infusion. Resting BP was measured twice during the medical interview before the study began. As previously described in detail (38), we demonstrated effective phentolamine application in this study by BP and heart rate assessment using Omron sphygmomanometry (Omron 773; Omron Healthcare Europe B.V. Hoedlorp, the Netherlands).

Substance Infusion

In the infusion study, we applied two sequential infusions with application of either saline or phentolamine for 1 minute (first infusion) and NE or saline for 15 minutes (second infusion), with an interval of 5 minutes between infusions. The postinfusion phase began after the second infusion.

To mimic NE stress reactivity effects, NE (Sintetica, SA, Mendrisio, Switzerland) was diluted in saline and the resulting solution of 5 μg/ml was infused with 1 ml/min for 15 minutes. In total, 75 μg of NE was administered. We chose a 15-minute infusion time for NE to parallel the duration of the TSST.

The nonselective α-adrenergic antagonist (i.e., α1- and α2-AR-blocker) phentolamine (Regitin; Novartis Pharma AG, Basel, Switzerland) was diluted in saline and 5 ml of 0.5 mg/ml, totaling 2.5 mg of phentolamine, was infused within 1 minute. Identical times of 1 minute and 15 minutes were used for saline infusions (38).

Physiological Measurements

Venous blood was drawn in EDTA-coated monovettes (Sarstedt, Numbrecht, Germany).

To assess granulocyte and monocyte numbers, as well as hematocrit and hemoglobin concentrations, five-part differential blood cell counts were obtained on automated hematology systems in the University Center for Laboratory Medicine and Pathology of the University Hospital Zurich (stress study: Advia 120; Bayer Diagnostics) and the University Institute of Clinical Chemistry of the Bern University Hospital (infusion study: Advia 120; Siemens Diagnostics). Notably, hematocrit and hemoglobin were assessed to control for confounding effects of potential stress- or infusion-induced hemococoncentration, i.e., plasma volume changes following previous methods (50).

For NE and EPI assessment, blood was immediately centrifuged for 10 minutes at 2000 g and 4°C; plasma was stored at −80°C until analyzed. Plasma NE and EPI levels were determined by means of high-pressure liquid chromatography using electrochemical detection after liquid-liquid extraction in the Laboratory of Stress Monitoring, Göttingen, Germany (51,52). The lower limit of a detection was 12 pg/ml each for EPI and NE; inter- and intra-assay CVs were less than 5%. Undetectable EPI values were replaced by half the detection limit. In two participants of the infusion study, some NE and EPI levels were missing because of technical problems with high-pressure liquid chromatography.

Statistical Analyses

Data were analyzed using SPSS (Version 23.0) statistical software package (SPSS Inc, Chicago IL) and presented as mean ± SEM (if not indicated otherwise). All tests were two-tailed with a level of significance of p ≤ 0.05. Before analyses, all raw data were examined for normal distribution using the Kolmogorov-Smirnov test. As some cell count data were skewed, all cell count raw data were logarithmically transformed for the analyses, but the original data are presented in the Tables and Figures for clarity.

We calculated body mass index (BMI) as the weight in kilograms divided by the square of the height. Mean arterial BP (MAP) was calculated from resting BP measurements using fully automated sphygmomanometry.
devices (Omron 773; Omron Healthcare Europe B.V., Hoofdorp, the Netherlands) using the formula 2/3 mean diastolic BP (DBP) + 1/3 mean systolic BP (SBP). Manipulation-induced changes in NE (NE change), EPI (EPI change), blood cell count (blood cell count change), and plasma volume percentage (plasma volume percentage change) were calculated as the difference in plasma levels between the peak, i.e., 1-minute after experimental manipulation (i.e., stress or infusion) and the respective baseline (i.e., before manipulation).

**Stress Study**

To test for stress effects on blood cell counts, catecholamines, and plasma volume, we calculated general linear models with repeated measurement. Associations between stress-induced catecholamine and blood cell count changes were calculated using linear regression analyses with EPI and NE stress change scores as independent variables controlling for age, BMI, and MAP. We controlled for these potential confounding variables because (a) of well-known age effects of stress on the sympathetic nervous system and the immune system (53), because (b) BMI was found to relate to neutrophil baseline counts (54) and altered stress-induced cytokine secretion by stimulated immune cells (46), and because (c) catecholamine stress reactivity was found to be higher in hypertensives (45).

**Infusion Study**

To test for differences between infusion trials in baseline NE and EPI concentrations, as well as blood cell counts, we calculated general linear models with repeated measurement, with the baseline levels of each trial as repeated dependent variables, and report post hoc tests to identify differences between trials (i.e., trial 1 versus 2, trial 1 versus 3, and trial 2 versus 3). Trial differences in NE and EPI changes, as well as plasma volume changes, were calculated accordingly.

To test the effects of the different infusion trials on blood cell counts over time, we compared trials pairwise (i.e., trial 1 versus 2, trial 1 versus 3, and trial 2 versus 3) by calculating general linear models with the two repeated factors trial (2 trials) and time (4 blood cell count time points). Moreover, we tested post hoc whether blood cell counts, catecholamines, and plasma volumes significantly changed over time in each trial by calculating general linear models with repeated measures in each trial separately. Post hoc tests comprised further of paired t tests to test for differences between baseline and the expected peak, i.e., 1 minute after infusions in each trial.

All blood cell count analyses are presented without and with adjustment for plasma volume changes following the respective experimental manipulation according to previous methods (50).

Effect size parameters (f) were calculated from partial $\eta^2$ values and are reported where appropriate (effect size conventions: f = .10 = small, .25 = medium, .40 = large).

**RESULTS**

**Participants’ Characteristics**

As depicted in Table 1, study participants were men varying in age, BMI, and MAP.

**Baseline Measures and Treatment-Induced Changes in Catecholamines and Plasma Volume**

Table 2 summarizes baseline cell counts in the two studies and treatment-induced changes of both catecholamine concentrations and plasma volume percentages.

**Stress Study**

**Stress-Induced Changes**

As previously described (55), stress induced significant increases in NE ($F(1/43) = 136.57, p < .001, f = 1.78, \eta^2 = .76$) and EPI ($F(1/43) = 22.68, p < .001, f = 0.73, \eta^2 = .35$) levels from baseline to immediately after stress (see Supplementary Fig. S1, Supplemental Digital Content 2, http://links.lww.com/PSYMED/A493). Plasma volume decreased in reaction to stress provocation ($F(2.75/118.21) = 49.90, p < .001, f = 1.08, \eta^2 = .54$) with lower values immediately after stress that recovered quickly.

**Infusion Study**

**Baseline Measures**

As shown in Table 2, there were no baseline (i.e., preinfusion) differences between the three trials in terms of granulocyte and monocyte numbers as well as plasma catecholamines ($p$'s $\geq .17$).

**Infusion-Induced Changes**

Both saline+NE and phenolamine+NE led to increased NE levels compared with saline+saline ($p$'s $< .001$), whereas NE changes did not differ between saline+NE and phenolamine+NE ($p = .79$). Saline+NE led to decreased EPI levels compared with saline+saline ($p = .013$) and phenolamine+NE ($p = .027$), whereas EPI changes were similar between saline+saline and phenolamine+NE ($p = .75$). Comparisons between trials showed significant differences in infusion-related plasma volume percentage changes ($F(2/40) = 24.063, p < .001, f = 1.10, \eta^2 = .55$) between saline+NE and saline+saline ($p < .001$), between phenolamine+NE and saline+saline ($p < .001$), as well as between saline+NE and phenolamine+NE ($p = .005$). Both saline+NE ($F(2.73/54.61) = 22.63, p < .001, f = 1.06, \eta^2 = .53$) and phenolamine+NE ($F(2.84/56.75) = 21.37, p < .001, f = 1.03, \eta^2 = .52$) led to decreased plasma volume over time; saline+saline, however, increased plasma volume over time ($F(1.9/38.0) = 5.08, p = .012, f = 0.50, \eta^2 = .20$).

**Stress Study: Blood Cell Count Reactivity to Stress and Associations With Catecholamine Stress Responses**

Stress induced significant increases in all granulocyte types (neutrophils: $F(2.94/126.29) = 23.04, p < .001, f = 0.73, \eta^2 = .35$; eosinophils: $F(2.45/105.32) = 3.75, p = .019, f = 0.29, \eta^2 = .08$; basophils: $F(2.57/110.51) = 3.47, p = .024, f = 0.28, \eta^2 = .08$), and monocytes ($F(3.00/129.00) = 29.18, p < .001, f = 0.82, \eta^2 = .40$) with highest cell counts immediately after stress (Fig. 1). Correcting for hemoconcentration did not significantly change results for neutrophils and monocytes ($p$'s $< .001$), but basophil increases became of borderline significance ($p = .079$) and eosinophil increments were no longer significant ($p = .74$).

Linear regression analyses revealed that independent of age, BMI, and MAP, higher NE stress changes, but not EPI stress changes, related to higher neutrophil stress changes without

Sa = saline; NE = norepinephrine; Ph = phenolamine; EPI = epinephrine.
Values are given as means (standard deviation, range). Change scores are calculated as post- (i.e., 1 minute after the respective treatment) minus baseline measurements. Post hoc tests of general linear models with repeated baseline or change measures were conducted to test for trial differences in baseline values and change scores. Bold values indicate significance. n = 20. * n = 19.
In response to psychosocial stress, we found immediate transient increases in neutrophil and monocyte numbers with and without plasma volume change correction. Notably, we corrected for hemoconcentration because changes in plasma volume can...
confound cell count measurements (56). Our observation is in line with other studies showing immediate increases of neutrophils and monocytes after various acute stress paradigms (10–17). The observed small-scale increases of eosinophil and basophil cell counts after stress were in line with observations in atopic dermatitis patients (10) but became insignificant after hemoconcentration correction.

The main finding of our stress study was that stress-induced plasma NE concentration increases related to the observed transient elevation of neutrophil cell counts immediately after stress cessation, but not thereafter. We were unable to find a second response of neutrophils, as has been reported 1 hour after stress cessation (3,14,18). The quick start and end of the stress-induced release of catecholamines (57) from both, adrenal medulla and sympathetic nerve endings, and their short half-life time in blood (e.g., $t_{1/2}(NE) = 2.5$ minutes in humans (58)) may explain this kinetic during and immediately after the stress test. In a previous study in young women, increments in EPI but not NE concentrations were associated with the total granulocyte numbers immediately after psychosocial stress, although this association vanished after hemoconcentration correction (29). Reasons for this divergence may relate to differences in age and sex and the intensity and duration of stress induction paradigms between studies.

**Infusion Study**

In the second study, we infused an amount of NE (trial 2, 75 μg) in a saline-controlled (trial 1) paradigm, which mimics the physiological stress response to the TSST in terms of NE release duration (15 minutes (57)), plasma volume changes (−3.4% (59)), and BP increases (38). Before any administration, neither catecholamine plasma levels nor cell counts differed between trials, so a randomization bias could be excluded.

With respect to innate immune cell numbers, we observed an increase of neutrophil granulocytes and monocytes immediately after NE infusion that was reduced by previous phentolamine application, particularly in neutrophils. Statistical correction for plasma volume changes confirmed increased neutrophil numbers

![Graph](image-url)
after NE infusion with and without α-ADR blockade. Significant differences for monocyte dynamics remained only after NE infusion without α-ADR blockade. Moreover, eosinophil but not basophil counts increased after NE infusion without α-ADR blockade, however, not independently of hemoconcentration. These results suggest that comparable with other in vivo NE infusion studies, we could validate an immediate NE-induced increase of monocytes (36) and neutrophils (30,36). In addition, in vivo EPI infusions led to immediate transient increases of monocyte and neutrophil cell counts (30–33,35,60). In line with other stress (10) and infusion (33) studies in healthy participants, we could not observe independent increases in eosinophil and/or basophil counts.

**Underlying Mechanisms**

With respect to underlying ADR mechanisms, our data suggest an inhibiting effect of α-ADR blockade by phentolamine on NE-induced mobilization of neutrophils and monocytes and that the phentolamine effect on monocytes but not on neutrophils did depend on hemoconcentration. To the best of our knowledge, no other study hitherto investigated effects of catecholamine infusion and α-ADR blockade on circulating granulocyte and monocyte numbers in humans in vivo. This is a novel finding in humans and concurs with our paradigm that α-ADR blockade did not completely inhibit NE-infusion–induced increases in neutrophil and monocyte counts, β-ADR pathways may also be involved in regulating changes in counts of these immune cells. So far, catecholamine infusion studies investigating β-ADR mechanisms suggest that β-ADR accounts for decreases or no effect rather than increases in numbers of circulating myeloid cells of the innate immune system. More precisely, β-ADR agonist infusion resulted in no change or lower numbers of circulating granulocytes and monocytes in humans (30,33). In line with this, in vivo co-administration of β-ADR blockers and NE or EPI, which enhance α-ADR activation, led to increased circulating neutrophil numbers in rats (61) but had no effect in humans (62). Overall, comparing other studies with our paradigm is limited because of different methodologies regarding substance amounts, infusion and sampling periods, and the lack of control for plasma volume changes (30–32,36). Furthermore, catecholamine applications in the supraphysiological range are difficult to interpret, because high concentrations of, e.g., NE, can disproportionally activate β-ADR and thereby override α-ADR effects (63) or even induce α-ADR desensitization (64).

We can only speculate about the origin of the observed cell number increases. The short duration of the stressor or the NE-infusion duration, respectively, make de novo cell differentiation processes as seen after chronic stress exposure (65) unlikely. Thus, mobilization effects on mature innate immune cells seem more likely. α-ADR expression is highly dynamic during the lifespan of innate immune cells and is inducible by ADR agonists (66). We, therefore, assume that via α-ADR mechanisms, NE can induce mobilization of mature myeloid immune cells transiently attached to endothelia in different organs framing the marginal pool (67,68). α- and β-ADR are expressed on myeloid immune cells, including neutrophils, monocytes, and macrophages (42,43,69), as well as on endothelial cells (70–72). Whereas previous research supports loss of cell-cell connection via β-ADR activation (62,73,74), our data also suggests an α-ADR mechanism to be involved in the observed increase of circulating cell numbers. Indirect α-ADR effects on myeloid immune cell numbers may result from increases in venous tone, peripheral resistance, and blood filtration causing hemoconcentration (56,75). In line with the latter, we indeed observed that a significant difference in monocyte increases between saline+saline and phentolamine+NE disappeared after correcting for hemoconcentration.

### Potential Functional and Clinical Significance of Stress-Related Increases in Circulating Numbers of Monocytes and Neutrophils

The potential functional and clinical significance of the observed acute stress-related transient increases in circulating absolute numbers of monocytes and neutrophils should be considered. Neutrophils and monocytes are the first line of cellular defense against pathogens, and under nonstress or basal conditions, only a part of these innate immune cells are patrolling in the blood stream (76). Absolute cell counts represent the detectable amount of the respective effector cells in the circulation and increases in innate immune cell counts represent more immune competent effector cells per blood volume unit and thus a greater effector cell concentration. If cell activity is not compromised, this may come along with a greater immune defense potential, at least transiently. Notably, increases in absolute cell numbers do not necessarily relate to cell percentage increases as the latter imply altered cell distribution but do not point to cell count increases or higher concentration of the respective cell types (compare Supplementary Tables S1 and S2, Supplemental Digital Content 4, http://links.lww.com/PSYMED/A495). In the sense of an unspecific immune reaction to acute stress (77), transient increases in circulating numbers of monocytes and neutrophils may reinforce the patrolling cells in the blood stream or traffic into organs to react faster to pathogens or tissue damage (e.g., (78)). This enforced immune reactive potential may represent a clear evolutionary benefit in acute injury situations, such as physical encounters or upcoming surgeries, where immune enhancement accelerates healing. However, in other stressful situations, an increased immune preparedness may potentially have clinical consequences (e.g., in transplantation surgery where immune suppression is warranted). Particularly, in vulnerable persons, such as patients with cardiovascular disease or other inflammatory diseases, acute increases in monocyte and neutrophil counts and related activity may trigger disease events such as acute coronary syndromes (79,80). In addition, repetitive increases in numbers of innate immune cells due to repeated or chronic stress may, according to the model of allostatic load (26), accumulate over time and result in elevated basal monocyte and neutrophil numbers (65). Moreover, because effector functions of monocytes and neutrophils include cytokine production, (22,25) elevated numbers of these cells may induce a systemic low-grade inflammatory state having adverse health consequences, including cardiovascular disease (e.g., (27)).

### Strengths, Limitations, and Conclusions

The major strength of our studies is the combination of cross-sectional with specific causality in vivo assessment in humans. We applied a NE-infusion design that mimics physiological NE-stress reactivity effects in terms of duration and dosage in an appropriate sample size and with appropriate Latin Square trial
balancing sequence. We controlled for hemococoncentration in both studies. Because neither NE (81) or phentolamine (82) cross the blood brain barrier, there is no interference with central nervous effects in the infusion study and we interpret our findings as peripheral. We can exclude EPI as a confounding factor in NE-infusion-induced cell number increases, because EPI levels did not concomitantly increase after NE infusion. Our studies also have some limitations. We infused the same NE dosage in all participants, which can increase interindividual variability of the immune cell number reactivity and thus the risk of nonsignificant findings. The risk of family-wise type I error due to multiple testing cannot be excluded. After NE infusion, we measured approximately five times higher NE plasma concentration increases than after TSST exposure. However, during the infusion study, we did not observe EPI increases excluding concomitant activation of the SAM axis and resulting additional release of NE from sympathetic nerve endings. As indicated by BP increases from baseline to TSST performance (stress study: SBP: 13.37 ± 23.82 mm Hg, DBP: 11.69 ± 17.07 mm Hg) or from 10 minutes before infusion begin to maximum values during NE infusion (infusion study trial 2: SBP: 10.38 ± 9.85 mm Hg, DBP: 4.76 ± 6.53 mm Hg), the net efficiency of NE is slightly lower in the infusion study, suggesting successful NE application within the physiological stress response range. Future studies are needed to replicate these findings in women and other populations, to address ADR mechanisms beyond nonselective α-ADR blockade, to clarify the origin and subset of the observed cell number increases, and to investigate the clinical relevance of the transient increase in innate immune cells. In summary, our findings suggest that the mechanisms underlyings stress-induced immediate increases in neutrophil and monocyte numbers in humans involve NE and at least in part α-ADRs. From an evolutionary perspective, this mechanism concurs with the fight-or-flight-paradigm and could have been helpful for survival after potential tissue damage. Increased stress-induced patrolling of the fight-or-flight-paradigm and could have been helpful for survival from an evolutionary perspective, this mechanism concurs with the fight-or-flight-paradigm and could have been helpful for survival after potential tissue damage. Increased stress-induced patrolling of myeloid innate immune cells, notably with phagocytic features (22,25), likely increase the immune defense, thereby counteracting pathogen invasions and infections.

The authors thank Renata Bünter, Regula Dänzer, Regula Jaeggi, and Ursina Sager from the Clinical Investigation Unit of the Bern University Hospital, Inselspital, for their help in the conduct of the study. The authors also thank Anke and Graham McIntosh for language editing of the revised manuscript.

Sources of Funding and Conflicts of interest: This study was funded by research grants from the Swiss National Science Foundation (PP00P1_128565/1 and 320030_122406) and from the German Research Foundation (INST 38/550-1) (all to PHW). The funding sources had no impact on study design, data collection and analyses, the writing of the manuscript, or the decision to submit the manuscript for publication. The authors report no conflicts of interest.
